THESIS ABSTRACT

Lucy Kathleen Walsh

Master of Science

Department of Geological Sciences

December 2012

Title: Implications for Volcanic Hazards in the Central and Southern Cascades Based on Gas Emissions During Explosive Cinder Cone Activity

Volatile emissions from Cascades cinder cone eruptions have been well-documented; however the implications for understanding the effects that volcanic gases have on surrounding communities have not been addressed. This study examines the hazards from volatile degassing during explosive activity by (1) analyzing S, Cl, and F concentrations dissolved in olivine-hosted melt inclusions and matrix glass from cinder cones located in central Oregon and northern California, (2) estimating the mass of volcanic gas degassed during these eruptions, and (3) predicting gas concentrations downwind of the vent. Analyses reveal that the magmas degassed >88% S, <49% Cl, and <50% F during eruption, equating to a release of ≤ 4.5 Mt SO₂, ≤ 0.2 Mt HCl, and ≤ 0.2 Mt HF. Predictions of gas concentrations downwind of the vent provides reassurance that the levels of volcanic gases were not high enough at the time of eruption to present acute or severe health hazards to nearby residents.

CURRICULUM VITAE

NAME OF AUTHOR: Lucy Kathleen Walsh

GRADUATE AND UNDERGRADUATE SCHOOLS ATTENDED

University of Oregon, Eugene, OR
University of Washington, Seattle, WA
Gonzaga University, Spokane, WA

DEGREES AWARDED:

Master of Science, Geological Sciences, 2012, University of Oregon
Bachelor of Science, Earth and Space Sciences, 2009, University of Washington

AREAS OF SPECIAL INTEREST:

Physical volcanology
Geochemistry

PROFESSIONAL EXPERIENCE:

Graduate Teaching Fellow, University of Oregon, 2010 to present
Research Assistant, Pacific Northwest Seismic Network, 2007-2010
Teaching Assistant, Department of Earth and Space Sciences, University of
Washington, 2009

GRANTS, AWARDS, AND HONORS:

Graduate Teaching Fellowship, Geological Sciences, 2010 to present
Johnston Scholarship, University of Oregon, Department of Geological Sciences,
2011

ACKNOWLEDGMENTS

I wish to express my sincerest gratitude to Paul Wallace for granting me the opportunity to contribute research to a topic that I truly care about. I would also like to thank Paul for his guidance over the last two years- I am a better scientist because of his efforts. Thank you to Kathy Cashman, Dana Johnston, and Daniele McKay for their invaluable insight and their commitment to the success of my Masters Thesis. I owe special thanks and appreciation to Marli Miller and Dave Blackwell. Thank you Marli for being the first faculty member that made me feel like a peer. Your willingness to share your own graduate experiences will forever be of value to me as it taught me to take setbacks with grace and confidence. A very big thank you to Dave Blackwell, for whom I hold the greatest respect for. Dave, you have been such a tremendous mentor. You taught me the importance of teaching- the importance of caring about students and peers such that you give them a better chance at success. Thank you for your confidence in my teaching abilities and your tireless efforts on the behalf of your students and GTFs.

To my family, who has never ceased to amaze me in their support of everything I do, even during times I can't muster up my own self-confidence. I would not be the woman I am today without your love. Thank you for trusting in my decisions and being there for me every day- I love you. Thanks to Mike for also being there every step of the way and for acting as my rock and my reason for both perseverance and procrastination. I would also like to thank many graduate students, and more importantly, my good friends who made these last two years so enjoyable. Thank you to my officemate Ryan who's fro-yo runs, late night pump up sessions, and kind words help define my graduate experience. Thank you to Stan, Angie, and Dana for Bachelor nights, caring for

inebriated field camp students, epic dodgeball birthdays, excuses to chat instead of work, and your irreplaceable friendships. Finally, I would like to thank Cindie Judy and her Rec team for providing me with no t-shirt, but a great set of memories with my fellow grads.

To Grandpa Joe and Granddaddy Walsh, whose endless love and support lives within me.

CHAPTER I

INTRODUCTION

The relationship between magmatic volatiles and the hazards they pose to surrounding communities is one of the least understood aspects of explosive cinder cone eruptions. The main focus of studies concerning magmatic volatiles erupted at cinder cones has been on volatile recycling by subduction, formation of arc magmas, and the effects of shallow degassing on eruption styles (Leeman et al., 1990; Conrey et al., 1997; Johnson et al., 2008; Keating et al., 2008; Vigouroux et al., 2008; Di Traglia et al., 2009; Pioli et al., 2009; Ruscitto et al., 2010). Along the central and southern Cascade Arc, magmatic volatiles like H₂O, CO₂, S, and Cl have been studied at mafic cinder cones to better understand the geochemical and geophysical processes listed above (e.g. Wallace, 2005; Le Voyer et al., 2010; Ruscitto et al., 2010). However, the implications for understanding the effects that volcanic gases can have on surrounding communities during eruption, especially the effects of fluorine, have not been addressed.

During eruption, typical gas species emitted include water vapor (H₂O), carbon dioxide (CO₂), sulfur dioxide (SO₂), hydrogen chloride (HCl), hydrogen fluoride (HF), hydrogen sulfide (H₂S), carbon monoxide (CO), radon (Rn), and heavy metals including lead and mercury (Hansell and Oppenheimer, 2004). Health hazards from the emission of water vapor are minimal, so most research on gas exposure to date has focused on exposure to CO₂, H₂S, and SO₂ from degassing of volcanic and geothermal sources (Hansell et al., 2006). For this reason, I concentrate on the health effects from degassing

of the more poorly understood gases HCl and HF. I include SO₂ in my analyses as well so I can better compare gas contents in the Cascades to other volcanic centers worldwide.

A wide array of hazardous effects have been documented at active volcanic centers (e.g. Auckland Volcanic Field, New Zealand; Coote et al. 1997; Rhoades et al. 2002; Bebbington and Cronin 2011). These effects have also been inferred using tools such as geologic mapping and geochemical analyses of erupted materials for prehistoric eruptions (e.g. Cerro Negro, Nicaragua; Hill et al. 1998; McKnight and Williams 1997). Real-time measurements of gas composition and flux released from actively erupting volcanic centers have been measured using ground-based remote sensing methods. For example, Correlation Spectrometry (COSPEC) can measure SO₂ concentrations in tons/day. Cinder cone eruptions in the Cascades are all prehistoric, and because the most recent cinder cone eruptions in the Cascades occurred long before modern instrumentation, real-time measurement cannot be employed. Instead, volatile fluxes from these past eruptions can be estimated by analyzing melt inclusions trapped within olivine phenocrysts and rapidly quenched tephra matrix glass.

Studies on cinder cone degassing suggest such eruptions can produce volatile emissions at concentrations high enough to pose significant health hazards (e.g. Stoiber and Rose, 1973; Cronin and Sharp, 2002; Delmelle et al., 2002). However, the majority of these studies focused on inhalation or ingestion of volcanic gases and aerosols by livestock and flora; therefore not much is known of the effects on humans. This emphasizes the importance of such a study in a volcanically active and populous region such as the Cascades. Cinder cones are also the most common volcanic landform on Earth, and the relatively short recurrence rates of cinder cone volcanism in some regions

(e.g. Michoacán-Guanajuato volcanic field, 2×10^{-3} vents/year; Connor and Conway, 2000) increase the probability of human experience with cinder cone hazards. The central and southern Cascade arc is an ideal study site because it has a wealth of geochemical and geophysical data already in existence, it has relatively young, numerous, and well-preserved cinder cones, and it is host to major urban population centers.

Data presented in this thesis from analysis of dissolved volatiles in olivine-hosted melt inclusions and quenched matrix glass are used to address the following questions:

- (1) What are the pre- and post-eruptive volatile concentrations of S, Cl, and F in the magmas erupted from cinder cones located in central Oregon and northern California?
- (2) How do S, Cl, and F concentrations in the central and southern Cascades arc magmas compare to those from other arcs worldwide?
- (3) What are the concentrations of SO₂, HCl, and HF likely to be experienced at ground level in communities downwind of the vent during a sustained explosive cinder cone eruption?
- (4) Are these concentrations of SO₂, HCl, and HF elevated above World Health Organization (WHO) and Occupational Safety and Health Administration (OSHA) maximum exposure limits?
- (5) Knowing the gas concentration downwind of the vent, will city governments in central Oregon and northern California need to prepare for hazardous effects to agriculture or human life?

Substantial work on across-arc volatile concentrations has been carried out in the central and southern Cascades. Extensive melt inclusion analyses and bulk lava analyses

were performed by Ruscitto et al. (2010) and Ruscitto (2011) at the University of Oregon. However, the fluorine analyses had relatively large analytical errors, and therefore were not considered to be reliable. For this study, I developed a modified procedure for F analysis with considerably less error using a LTAP diffraction crystal on the Cameca SX100 in the CAMCOR facility on the University of Oregon campus. A secondary basaltic glass standard with low F concentration was used to assess accuracy of F detection. The goal of this dissertation is to use this increased precision to modify current expectations of cinder cone hazards to human, livestock, and agricultural industries for surrounding communities in the central and southern Cascades.

CHAPTER II

OVERVIEW OF CINDER CONE VOLCANISM, TECTONIC SETTING, AND MAGMA GEOCHEMISTRY IN THE CASCADES ARC

2.1. Cinder cone eruptions

A cinder cone is a mafic volcanic structure that forms by the eruption of low-viscosity basaltic magma (Vespermann and Schmincke, 2000). It is comprised of unconsolidated walls formed from ballistic deposition and subsequent slumping as the angle of repose is exceeded. The walls are composed of scoria, a mafic eruption product ejected from the vent as gas within the magma rises, expands, and bursts. Internal to a cinder cone is a central vent and a welded core (Wohletz and Heiken, 1992). Cinder cones have relatively simple magmatic plumbing systems consisting typically of a central feeder dike and radial dikes that transport magma from the lower crust to the surface (Keating et al., 2008; Hintz and Valentine, 2012). Cinder cones are commonly monogenetic (single eruptive episode), however polygenetic eruptions from a single vent have been documented (e.g. Cerro Negro, Nicaragua). Eruptions can last weeks to years, as seen at Parícutin, Mexico, which continuously erupted from 1943 to 1952. Eruptions vary between Hawaiian-type eruptions (no ash column; lava flows and fire fountaining) to Violent Strombolian-type eruptions (≤ 10 km high ash columns and lava flows) (Vergnolle and Mangan, 2000; Pioli et al., 2008).

Cinder cones erupt a variety of material that ranges in size, composition, and physical properties. Tephra is defined as magmatic fragments erupted from a cinder cone and can range in coarseness from bomb- (>64 mm) to ash-size (<2 mm). Tephra is

ejected from the vent during periods of explosive activity. Depending on the explosivity of an eruption, tephra can travel 100's of kilometers away from the vent. Tephra cools quickly as ambient air temperatures are much cooler than magmatic temperatures. This large temperature gradient causes very rapid quenching and creates a glass matrix that retains some dissolved volatiles, typically less than the concentration in the parent magma. Lava is fluid magma released during periods of effusive eruption. Lava is transported to the surface by radial dikes and is erupted at the base of cinder cones. Lava crystallizes slowly when it reaches the surface as heat is lost through the top of the flow allowing volatiles to readily escape.

2.2. Olivine-hosted melt inclusions

The mineral olivine is transported from depth and erupted simultaneously with tephra and lava. Olivine is commonly the first mineral, along with Cr-spinel, to crystallize from a basaltic melt. Olivine-hosted melt inclusions commonly form during pulses of rapid crystal growth, and data for suites of melt inclusions often show evidence for polybaric crystallization of the rising magma. The pulses of rapid growth create embayments that can subsequently trap melt as the olivine crystal continues to grow (Roedder, 1984; Metrich and Wallace, 2008). These small volumes of silicate melt trapped within the olivine crystals are known as olivine-hosted melt inclusions. A melt inclusion is relatively unaffected by external changes once it is formed and therefore records a snapshot in time of magma composition at depth. Changes to major element and volatile concentration can occur within a melt inclusion if the melt inclusion is allowed to cool slowly. During cooling, post-entrapment crystallization of the melt

inclusion can increase concentrations of incompatible elements, including volatiles (Roedder, 1984; Sisson and Layne, 2003). Segregation of the melt into a separate liquid and gas phase can also occur inside the melt inclusion when the pressure in the melt inclusion drops below the vapor saturation pressure of the melt contained at a certain temperature. These shrinkage bubbles, or vapor bubbles, greatly decrease the concentration of volatiles with low solubility (e.g. CO₂) as they diffuse from the trapped melt into the bubble (Roedder, 1984; Metrich and Wallace, 2008). However, it is unlikely the shrinkage bubbles will affect S, Cl, or F as these volatiles have high solubilities within the melt. Lastly, hydrogen is susceptible to diffusion into and out of the olivine after entrapment, which can affect overall H₂O concentrations (Portnagin et al., 2007), but again, no evidence suggests such effects with S, Cl, or F concentrations.

During eruption, volatiles are initially released into the atmosphere as gases, but depending on the time spent within the plume, the density of ash particles, and temperature, a gas can transition into an aerosol – a fine solid or liquid particle suspended in gas (Mather et al., 2003). Formation of aerosols can occur in a variety of ways, most commonly as volcanic gases cool and condense to form particles, adsorb onto surfaces of existing particles, and dissolve into pre-existing aqueous phases (e.g. water droplets). Scavenging by silicates can be an important sink for volcanic volatiles during eruption as documented at Fuego Volcano where up to 33% S and 17% Cl were rapidly deposited to the ground after adhering to ash with the convective plume (Mather et al., 2003). Aerosols that adhere to the surface of such tephra grains can be deposited great distances from the vent (Oskarsson, 1980). Acidic gases undergo acid-base reactions within the plume that can enhance gas uptake in an aqueous phase. An aqueous phase is likely

already present in the ambient air that mixes with the plume, and the high solubility of HCl and HF, and moderate solubility of SO₂ and H₂S makes it easy for these gas species to dissolve into that aqueous phase (Mather et al., 2003; Textor et al., 2003). Modeling of stratospheric volcanic gas scavenging by water droplets in the Laacher See eruptive plume by Textor et al. (2003) suggested almost complete depletion of HCl in the plume with insignificant scavenging of SO₂. However, gas scavenging models from Aiuppa et al. (2006) in the troposphere show only minor HCl dissolution into an aqueous phase or adsorption onto a particle surface during short-term transport (e.g. traverse of several kilometers in tens of minutes). SO₂ and H₂S were also conserved during short-term transport. It is unclear why the process of gas scavenging in the stratosphere differs from the troposphere, but Textor et al. (2003) and Mather et al. (2003) propose the differences may be due to the percent water and temperatures necessary to drive reactions within the plume. Since Strombolian to Violent Strombolian plume heights rarely extend past the troposphere, it is unlikely that the volatiles released from these cones transitioned into an aerosol phase. For the sake of clarity, I will refer to the volatiles released from the vent into the eruptive plume as gases.

2.3. Tectonic setting

The Cascades volcanic arc extends 1,250 km from northern California to southern British Columbia. The arc consists of well-separated, NNW trending volcanic vents that have erupted basaltic to rhyolitic lava compositions since the onset of volcanism at 40 Ma when the ancient, oceanic Farallon Plate docked with North America. Broken into three segments, Quaternary volcanism occurs today as the Explorer Plate (north), the Juan de

Fuca Plate (central), and the Gorda Plate (south) actively subduct beneath the North American plate (Figure 1).

Seismic tomography, geochemical, and geodetic studies of the Cascadian arc have constrained the slab dip angle, the crustal thickness of the arc, the convergence rate, and convergence angle of subduction and suggest the Cascadian subduction zone is relatively warm, young, and slow (Kirby et al., 2002; Stern, 2002). A warm slab environment is one in which young oceanic lithosphere subducts at slow to moderate rates (Kirby and Wang, 2002). The Cascades volcanic arc is a global end-member of warm-slab subduction resulting from the slow subduction (35 mm/yr) of the young Juan de Fuca plate beneath Western North America (Ruscitto et al., 2010). The dip of the Juan de Fuca plate is calculated to be $<20^\circ$, with conservative constraints of $13\text{-}16^\circ$ (Trehu et al., 1994; Kirby et al., 2002). Estimates of North American crustal thickness above the subducting plate vary from 15 km off the coast of Oregon to 40 km beneath the High Cascades (Trehu et al., 1994). The basement beneath the Cascades from central Oregon to southern Washington consists of an oceanic terrain known as “Siletzia”, which is believed to have accreted to northern Oregon at ~ 50 Ma (Trehu et al., 1994). Accretion of Siletzia to present day Oregon has induced a clockwise rotation of the Oregon forearc. The rotation of this rigid block is thought to be responsible for the intra arc E-W extension along the crest of the Cascades and in the back arc (Taylor, 1990; Ruscitto, 2011).

Along with western encroachment of the Basin and Range extension in the Cascadian backarc, the central and southern segments of the Cascade arc have an estimated extension rate of 1 mm/yr (Schmidt and Grunder, 2009). Most of the extension in the back arc is accommodated in the form of either linear normal faults or horst and

Figure 1: Location map of the Cascadian subduction zone adapted from Bacon et al., 1997. Surface expression of faulting (red line) and active stratovolcanoes (orange triangle) associated with subduction. Abbreviations for volcanoes include: (M) Meager Mountain; (C) Mount Cayley; (G) Mount Garibaldi; (B) Mount Baker; (GP) Glacier Peak; (R) Mount Rainier; (SH) Mount St. Helens; (A) Mount Adams; (H) Mount Hood; (J) Mount Jefferson; (TS) Three Sisters; (NC) Newberry Crater; (CL) Crater Lake; (ML) Medicine Lake; (S) Mount Shasta; (L) Lassen Peak. Dashed red boxes indicate areas of focus within this study.

graben structures. The central Oregon Cascades is bounded to the west and east by a continuous arc-parallel graben known as the High Cascades Graben (Conrey et al. 1997). In central Oregon the majority of volcanism occurs within this High Cascades Graben. To the south in northern California a similar graben exists and is referred to as the Hat Creek Graben. Like the High Cascades Graben, Hat Creek Graben is defined by similar extensional regimes and houses the majority of extension-related volcanism within the region. Opening of the Cascadian back arc has produced prolific mafic volcanism in central Oregon and northern California.

Holocene volcanic activity in areas of the Cascades undergoing extension has formed small, isolated batches of basaltic and basaltic-andesite magmas erupted from extensive chains of cinder cones, small shields, and fissure-fed lava flows along pre-existing faults (Hughes & Taylor, 1986; Sherrod et al., 2004; Ruscitto, 2011). The focus of my research includes both the central Oregon Cascades (Three Sisters Volcanic Field) and the northern California Cascades (Lassen Volcanic Field). The density of Quaternary volcanoes in the central Oregon Cascades alone is extraordinary (1,054 vents in ~9500 km²; Hildreth 2007) (Figure 2). Only Michoacán, Mexico, southern Washington and northern California are comparable in terms of volcano density (Hildreth 2007). In the Three Sisters Volcanic segment alone, 466 Quaternary volcanoes cover the 90 km long landscape. In northern California, the Lassen Volcanic Field is distinguishable from other fields within the southern Cascades arc, most notably the Shasta field, by a 50 km gap along the arc crest that contains no Quaternary volcanic edifices. The Lassen Volcanic Field contains approximately 476 volcanoes that cover a ~6500 km² area.

Greater than 85% of all Quaternary volcanic edifices in the Three Sisters Volcanic Field and the Lassen Volcanic Field erupted basaltic to andesitic lavas (Hildreth, 2007).

The types of mafic lavas in the central and southern segments of the Cascades arc include low-K tholeiites (LKT), ocean island basalts (OIB), and calc-alkaline basalts (CAB). Each type indicates heterogeneity in mantle compositions and melting processes. LKTs probably form by a high degree of decompression melting of a depleted magma source. LKT magmas are also synonymous with high-Al olivine tholeiites (HAOT) and have some similarities to mid-ocean ridge basalts (MORB) (Ruscitto et al. 2010). OIBs are derived from an enriched mantle source that has high concentrations of high field strength elements such as Zr and Nb (e.g. Münker et al., 2004; Rowe et al., 2009). CABs represent mantle wedge melting with contributions from slab-derived fluids (Miyashiro, 1974; Leeman et al., 1990; Bacon et al., 1997; Leeman et al., 2005; Ruscitto et al., 2010). The combination of subduction and intra-arc extension along and off the arc axis has resulted in the eruption of LKTs, OIBs, and CABs in central Oregon and northern California.

Figure 2: Cinder cone density map for the central Oregon Cascades adapted from Schmidt and Grunder, 2009. Yellow circles denote single cinder cone vents, black triangles denote volcanic edifices, green shaded areas represent the extents of volcanic deposits, red shapes denote airports, black squares represent the location of popular central Oregon cities, and black lines denote major highways. Abbreviations for volcanic edifices include: (TFJ) Three Fingered Jack; (BB) Black Butte; (MW) Mount Washington; (BC) Belknap Crater; (NS) North Sister; (MS) Middle Sister; (SS) South Sister; (MB) Mount Bachelor; (NC) Newberry Crater. The dissected topography to the west represents the western edge of the High Cascades Graben. Within the graben cinder cones erupt along chains associated with normal fault rifting of the back-arc basin.

CHAPTER III

SAMPLE LOCATIONS AND DESCRIPTIONS

3.1. Sample characteristics

I selected tephra samples from cinder cones in the central Oregon and northern California Cascades based on the following criteria: (1) previous geochemical work by Ruscitto (2011) showing that many cones in central Oregon had a relatively simple magmatic history, allowing for simple mass-balance calculations, (2) a range of basaltic compositions throughout the arc, (3) eruption deposits of relatively young age (late Holocene) such that the tephra deposit was relatively intact, allowing for accurate estimate of eruptive volume and eruption characteristics, and (4) location of the cone within a critical distance of large populations centers or busy tourist communities. A detailed summary of each cone can be found in Appendix A.

The cinder cones included in this study are Collier Cone, Yapoah Crater, Four-in-One Fissure, Garrison Butte, Cinder Cone, Basalt of Old Railroad Grade (BORG), and Basalt of Highway 44 (BAS44). Figures 3 and 4 show the geographical locations of these cinder cones. Most of the cones studied erupted basaltic to basaltic andesite tephra and lava. The style of eruption ranges from Strombolian to Violent Strombolian, with the exception of Four-In-One Fissure, which is thought to have periods of Hawaiian-style eruptions (Marks, 2012; McKay, 2012). Dense rock equivalent (DRE) eruptive volumes range from 0.03-0.36 km³ (Clynne, 2011; Muffler et al., 2011; Marks, 2012; McKay, 2012 ;), however these are minimum estimates as weathering has mostly likely eroded the deposits. Cone height is trimodal- all cones are roughly 40 m, 80 m, or 150 m in height.

Figure 3: Location map of Collier Cone, Yapoah Crater, Four-In-One Fissure, and Garrison Butte. Grey shaded areas outline the cone (or volcanic) edifice; lava flows of each cone are outlined in color. Lava flows associated with Garrison Butte are highly vegetated and the extent of the flows has not been mapped. Dashed line traces the western edge of the High Cascades Graben.

Figure 4: Location map of Cinder Cone, Basalt of Old Railroad Grade (BORG), and Basalt of Highway 44 (BAS44). Grey shaded areas outline the cone (or volcanic) edifice; lava flows of each cone are outlined in color. The small dashed line around the lava flow of BORG indicates an unknown flow boundary. The lava flow of BAS44 is highly vegetated and partially covered by younger flows from a cinder cone that sits on the SE flank of West Prospect Peak shield volcano. Dashed line traces the eastern edge of the Hat Creek Graben.

Figure 5: Isopach maps of Collier Cone and Four-In-One Fissure from McKay, 2012. Dashed lines indicate inferred tephra isopachs locations. Black circles represent locations where tephra thickness measurements were made; colored circles are locations where complete stratigraphy was described. Grey shaded areas outline the cone edifice. Underlay is provided by Google Maps.

Most of the tephra samples contain phenocrysts of olivine, plagioclase, and pyroxene with the exception of Garrison Butte. Tephra from Garrison Butte contains only olivine. Spinel occurs as mineral inclusions in most of the olivines and is also sometimes present within olivine-hosted melt inclusions. The lavas of Collier Cone contain silicic xenoliths similar in composition to the Obsidian Cliffs, a dacitic to rhyolitic flow originating from Middle Sister (Schick, 1994). Lavas at Cinder Cone also have entrained quartz xenocrysts and granitic xenoliths that are suggested to be from a Mesozoic(?) granite, possibly akin to the Sierra Nevadas, buried beneath the Lassen region. The granitic xenoliths have major and trace element compositions that are typical of the Sierra Nevada granitoids (Borg and Clyne, 1998). Geographical and geological characteristics of each cinder cone analyzed in this study can be found in Table 1. Major and minor element concentrations for the silicic xenoliths can be found in Table 2.

Extensive mapping and lithologic descriptions of Holocene tephra deposits from Collier Cone and Four-in-One Fissure have been completed by McKay (2012) (Figure 5). Before the research of McKay (2012), many of the central Oregon cinder cone tephra deposits had yet to be mapped. McKay (2012) presented tephra isopachs along with estimates of erupted volume of each deposit from Collier Cone and Four-in-One Fissure. Work by McKay (2012) is fundamental in understanding the total tephra thickness deposited by these cinder cones and the distances the tephra traveled within the buoyant eruption plume.

3.2. Sand Mountain: An unusual mafic eruption in the central Cascades

Sand Mountain is a cinder cone located in the Sand Mountain Volcanic Field (SMVF) of the central Oregon Cascades. The SMVF includes the Sand Mountain chain of vents, Nash and Little Nash craters, the Lost Lake chain of vents, and associated lava flows and tephra blankets (Deligne, 2012). Previous physical analysis on Sand Mountain by McKay (2012) has shown the occurrence of a phreatomagmatic eruption, with explosive behavior similar to what has been described as Subplinian, ~3000 ybp. McKay (2012) suggested that magmas interacted with ground water during eruption (the High Cascades is a groundwater-dominated system; Deligne, 2012), fragmenting the magma and allowing deposition of a 25 cm isopach ~20 km from the vent (Figure 6). For reference, Collier Cone's 25 cm isopach was deposited only ~5 km from the vent (Figure 5). McKay (2012) estimated the maximum eruptive volume of Sand Mountain to be 1.13 km³. This estimate includes trace deposits (<25 cm) that are not definitively correlated to Sand Mountain. However, McKay relates thinning trends of Sand Mountain tephra to that of the 1943-1952 eruption at Paricutin and the two deposits match surprisingly well. McKay concludes that until the trace deposits of Sand Mountain are definitely identified, Paricutin's thinning trend is a reliable estimate for Sand Mountain's maximum eruptive volume. This unusual widespread tephra deposit appears to represent the maximum probable tephra hazard for mafic activity in central Oregon.

I conducted preliminary analyses on Sand Mountain olivine-hosted melt inclusions and matrix glass for four units of the eruption deposit using the methods outlined in the following chapter and found higher concentrations of S, Cl, and F than in any of the other central Oregon and northern California cinder cones in this study (Figure

7). The analysis also revealed a complex system of melt inclusion formation by differing processes at variable depths (Ruscitto, 2011). I was unable to match melt inclusion compositions to tephra compositions because it appears that multiple olivines with different magmatic histories were erupted at the same time.

Figure 6: Isopach map of Sand Mountain from McKay, 2012. Dashed lines indicate inferred tephra isopachs locations. Black circles represent locations where tephra thickness measurements were made; colored circles are locations where complete stratigraphy was described. Grey shaded areas outline the cone edifice. Underlay is provided by Google Maps.

Figure 7: Volatile concentrations in olivine-hosted melt inclusions (filled circle), matrix glass (open diamond), and lava glass (open triangle) erupted from Sand Mountain, located in the central Oregon Cascades. Sand Mountain has an unusually large tephra deposit (maximum DRE eruptive volume is $\sim 1.13 \text{ km}^3$) and the S, Cl, and F concentrations are elevated above those of the cinder cones analyzed in this study.

CHAPTER IV

METHODS

To test whether cinder cone eruptions in the central and southern segments of the Cascade arc pose a significant hazard to adjacent communities I (1) analyzed olivine-hosted melt inclusions and matrix glass to determine the pre-and post-eruptive concentrations of dissolved sulfur, chlorine, and fluorine, (2) calculated a total atmospheric release (in Megatons) of S, Cl, and F using a method modified from Thordarson et al. (1996) and, (3) calculated the maximum downwind gas concentrations for a steady-state eruption using a Gaussian plume advection-dispersion-diffusion model.

Tephra samples from proximal vent deposits from the cinder cones described in Chapter III were collected by Dan Ruscitto, Paul Wallace, Katharine Cashman, and Michael Clyne. Loose olivine grains were picked from the tephra samples. Using a refractive index oil of 1.657 and a binocular microscope, olivine grains containing enclosed melt inclusions $>40\ \mu\text{m}$ were selected for analysis. The olivine grains were mounted with crystal bond on glass slides and sanded with fine grit paper until the melt inclusion(s) were intersected. The olivines were then then mounted onto 2.5 cm circular pucks and polished to obtain optimal surface smoothness. Tephra clasts of 2-4 mm size were also selected along with the olivine grains. These clasts were mounted in 2.5 cm circular pucks, impregnated with Buehler epoxy, and then polished. The types of samples selected for analysis are shown schematically in Figure 8.

Not to scale

Figure 8: Illustration showing the types of samples collected for analysis; adapted from Thordarson et al., 1996. Pre-eruptive volatiles are measured using olivine-hosted melt inclusions, formed within the magmatic chamber at depth. The olivines are erupted along with tephra during explosive activity. Glassy melt inclusions with no accessory phases (e.g. titanomagnetite) were picked from the erupted tephra to be analyzed. Tephra groundmass glass records post-eruptive volatile concentrations. Golden-colored tephra, with a high percentage of glassy matrix, was chosen to be analyzed. By comparing pre- and post-eruptive volatiles concentrations the total concentration of volatiles released during an eruption can be determined.

4.1. Analytical procedures

Melt inclusion and matrix glass compositions were determined using the Cameca SX100 electron microprobe (EPMA) housed in the CAMCOR facility at the University of Oregon. The Cameca SX100 is equipped with five wavelength dispersive spectrometers and for this study I used a LTAP, a LPET, and three PET diffraction crystals. The elements K, Si, Ti, and S were analyzed using PET diffraction crystals, while Cl and F were analyzed using LPET and LTAP diffraction crystals, respectively. Concentrations of Al_2O_3 , FeO^{T} , MnO, MgO, CaO, Na_2O , and P_2O_5 were necessary for matrix corrections for the probe analyses. I used the average analyzed melt inclusion values from each cone from Ruscitto et al. (2011) for the central Oregon Cascades (Appendix B, C) and from unpublished work by Walowski et al. and Rasmussen et al. for cinder cones in northern California (Appendix B, C). Ruscitto et al., (2011) and Clyne (2011) provided the average analyzed matrix glass values, respectively. Because of the small K- α peak produced by fluorine, the LTAP diffraction crystal was chosen to measure fluorine as it provides more surface area, resulting in a higher count rate and narrower F peak that does not overlap with larger, adjacent peaks such as P. The single element per spectrometer set up that I used on the SX100 electron microprobe yields less variance between point analysis of individual melt inclusions and greater reproducibility of volatile concentrations within one cinder cone than the analytical procedures used by Ruscitto (2011).

The standards that I used were orthoclase MAD-10 for K, NBS K-411 glass for Si, TiO_2 synthetic for Ti, pyrite UC #21334 for S, chlor-apatite for Cl, and fluor-phlogopite for F. Standard VG-2 USNM 111240/52 was used to check the accuracy of

fluorine analyses using the fluor-phlogopite standard. Operating conditions for the standards were a 10 μm diameter beam, 50 nA beam current, and 15 kV accelerating voltage. A mean atomic number (MAN) background intensity correction was applied to Si (standard and unknown), thus no high or low off-peak background was measured. On peak (and background high, low) counting times were as follows: K: 40 s (5,5); Si: 40 s (none); Ti: 40 s (10,10); S: 40 s (10,10); Cl: 40 s (10,10); and F: 40 s (10,10).

All olivine-hosted melt inclusions and matrix glasses were analyzed using a 10 μm diameter beam, 50 nA beam current, and 15 kV accelerating voltage. Major and minor elements for melt inclusion and matrix glass samples were analyzed as unknowns for the following on peak (and background high, low) counting times: K 80 s (10, 10); Si 40 s (none); Ti 160 s (80, 80) ; S 160 s (80, 80) ; Cl 160 s (80, 80) ; F 160 s (80, 80).

Two to three data points were collected for each individual melt inclusion. Three to five data points were analyzed for matrix glass samples. Time dependent intensity (TDI) element concentrations were applied to Si, Ti, S, Cl, and F to correct the effects of element migration during analysis as the high beam current may have been responsible for minor shifts in the element concentration. An S K- α shift was applied to the run to account for the difference in the S K α value between the standard and the unknown (Wallace and Carmichael, 1994).

Detection limits for the elements analyzed were calculated for a 95% confidence interval using a single point detection limit equation adapted from Love and Scott (1983) (Donovan et al., 2011):

$$CDL = ZAF * \frac{n}{IS} * \sqrt{IB} * 100 \quad (1)$$

where n is equal to the standard score (1=68%, 2=95%, 3=99.7%), IS , or the raw counts on the analytical (pure element) standard, is equal to:

$$IS = STCT * C_t * B_c \quad (2)$$

and, IB , or the raw background counts on the unknown sample, is equal to:

$$IB = UNBG * C_t * B_c \quad (3)$$

ZAF is a method for the matrix correction of x-rays emitted from a sample. The method outputs a value that quantifies the effects of atomic number (Z), absorption (A) and characteristic (and sometimes continuum) fluorescence (F) separately (Donovan et al., 2011). $STCT$ are the standard counts/sec for a specific element, $UNBG$ are the unknown counts/sec for a specific element, C_t is the count time for a specific element, and B_c is the background counts for a specific element. Since the standards used in these analyses are not pure, IS was divided by the K -factor to normalize to a pure standard concentration.

4.2. Volcanic degassing calculations

Research by Thordarson et al. (1996) on the historical Laki fissure eruption in Iceland from 1783 to 1784 AD presented a mass balance approach for calculating the total SO_2 , HCl , and HF degassed during the eruption. This calculation assumes a relatively simple magmatic plumbing system such that the olivine-hosted melt inclusions and matrix glass are cogenetic and therefore, closely related. By analyzing olivine-hosted melt inclusions, tephra matrix glass, and lava matrix glass they estimated pre-eruptive and post-eruptive volatile concentrations in Laki magmas. These estimates are minimum values, in that the calculation assumes that there was no pre-erupted vapor phase. Their

findings indicate that a greater release of volatiles occurred during eruption than had been previously estimated. The technique developed by Thordarson et al. (1996) served as model for the analytical and modeling research presented here, but was modified to include the effects of variable fractional crystallization and assimilation in the magmatic systems that I studied.

The total mass of a volatile species in a given erupted volume of magma (C) is estimated using total DRE eruptive cone and tephra volume (V_T), melt density (ρ_m) (taken to be 2750 kg/m^3 ; Thordarson et al. 1996), calculated concentration of the volatile of interest from a melt inclusion that represents the evolved melt concentration due to fractional crystallization, crustal assimilation, and no degassing (C_{adj} ; in weight fraction), volatile species' molecular weight (M) (e.g. SO_2 ; 64.064 g/mol), volatile atomic weight (A) (e.g. S; 32.066 g/mol), and fraction of crystals in the groundmass (x) :

$$C = \frac{V_T * \rho_m * C_{ol} * \left(\frac{M}{A}\right)}{10^9} * (1 - x) \quad (4)$$

The volatile mass fraction released (F) during eruption is calculated by:

$$F = 1 - \left[c_{matrix} * \left(\frac{1}{1 - f_A * \left(\frac{c_{ol}}{1 - f_M}\right) + f_A * c_{i,A}} \right) \right] \quad (5)$$

where c_{ol} is the measured volatile concentration in the least evolved melt inclusion, c_{matrix} is the measured volatile concentration in the matrix glass, $c_{i,A}$ is the concentration of the volatile species within the assimilant, and f_M is the extent of fractional crystallization, and f_A is the extent of crustal assimilation that together relate the bulk composition of the

least evolved melt inclusion and the matrix glass. By combining equation (4) and equation (5) the total mass of a volatile species lost to degassing is calculated by:

$$m_T = C * F \quad (6)$$

This method (Eq. 4-6) converts the wt% of each volatile lost from the magma into a mass, in Mt, of a gaseous compound released into the troposphere during the explosive phase of the eruption. The formula also takes into account the size of the eruption. This applies an inherent “scaling” for each eruption. Eruptive volumes for Yapoah Crater, Garrison Butte, and BAS44 are not known, so I calculated the mass of volatiles released during eruption based on an eruptive volume of Collier Cone (i.e. 0.04 km³). BORG’s estimated eruptive volume does not include the tephra deposit, only the cone.

No analysis of the volatile content in the silicic contaminants near North Sister or Lassen Peak has been performed. Therefore to proceed with the degassing calculations, I used average S, Cl, and F concentrations in the upper continental crust from studies by Hartman and Wedepohl (1993), Wedepohl (1995), and Rudnick and Gao (2003) for the variable $c_{i,A}$. A more detailed explanation can be found in the Volatile Evolution and Degassing section in the Discussion chapter.

4.3. Gaussian plume dispersal model

To calculate the concentration of hazardous volcanic gases downwind from the vent during a sustained eruption I employ a Gaussian plume model from a point source. The point source Gaussian plume model is a simplified steady-state plume model that assumes a Gaussian distribution of particle concentration or species concentration in a gas phase, a constant flux of material, a constant wind speed, a constant eddy diffusivity,

and conservation of mass (Figure 9). This equation has mainly been applied to chemical pollutants within a smoke stack plume, but here I apply the equation to volcanic plumes and volcanic gases. The gas concentration can be determined as a function of a 3-dimensional plane $\{x, y, z\}$ (Hanna et al., 1981):

$$C_0(x, y, z) = \frac{Q}{2\pi u \sigma_y \sigma_z} \left\{ \exp\left(\frac{-(z-h)}{2\sigma_z^2}\right) + \exp\left(\frac{-(z+h)}{2\sigma_z^2}\right) \right\} \left\{ \exp\left(\frac{-(y^2)}{2\sigma_y^2}\right) \right\} \quad (7)$$

where x is the distance downwind from the vent, y is the horizontal distance away from the plume centerline, and z is the vertical distance away from the plume centerline. Q is the mass eruption rate of a volatile, h is the “center point” height of the plume, and u is the wind speed. The spatial coordinates x , y , and z define locations along a trajectory downwind of the vent. I focused on values of x that corresponded to average distances between central Oregon and northern California cinder cones and major population or tourist centers. By defining y and z as zero, I calculated the concentration of volcanic gases (ppm) at ground level directly below the plume, a set distance downwind from the vent. Q was determined by converting the weight fraction of a volatile dissolved in the melt into a volatile mass eruption rate (VMER) using the maximum and minimum volatile mass released during eruption from Equation (6). I used the total DRE mass of the cone and tephra erupted (kg) and a magmatic mass eruption rate MER (kg/s) to calculate the total eruption time (s), and with this value I converted the Mt released of S, Cl, and F in an eruption rate for each volatile (kg/s). Estimates of MER were adapted from Pioli et al. (2008, 2009) who concluded that MER drives eruption styles and Violent Strombolian eruptions occur with $10^3 < \text{MER} < 10^5$ kg/s. For this model, I estimated a

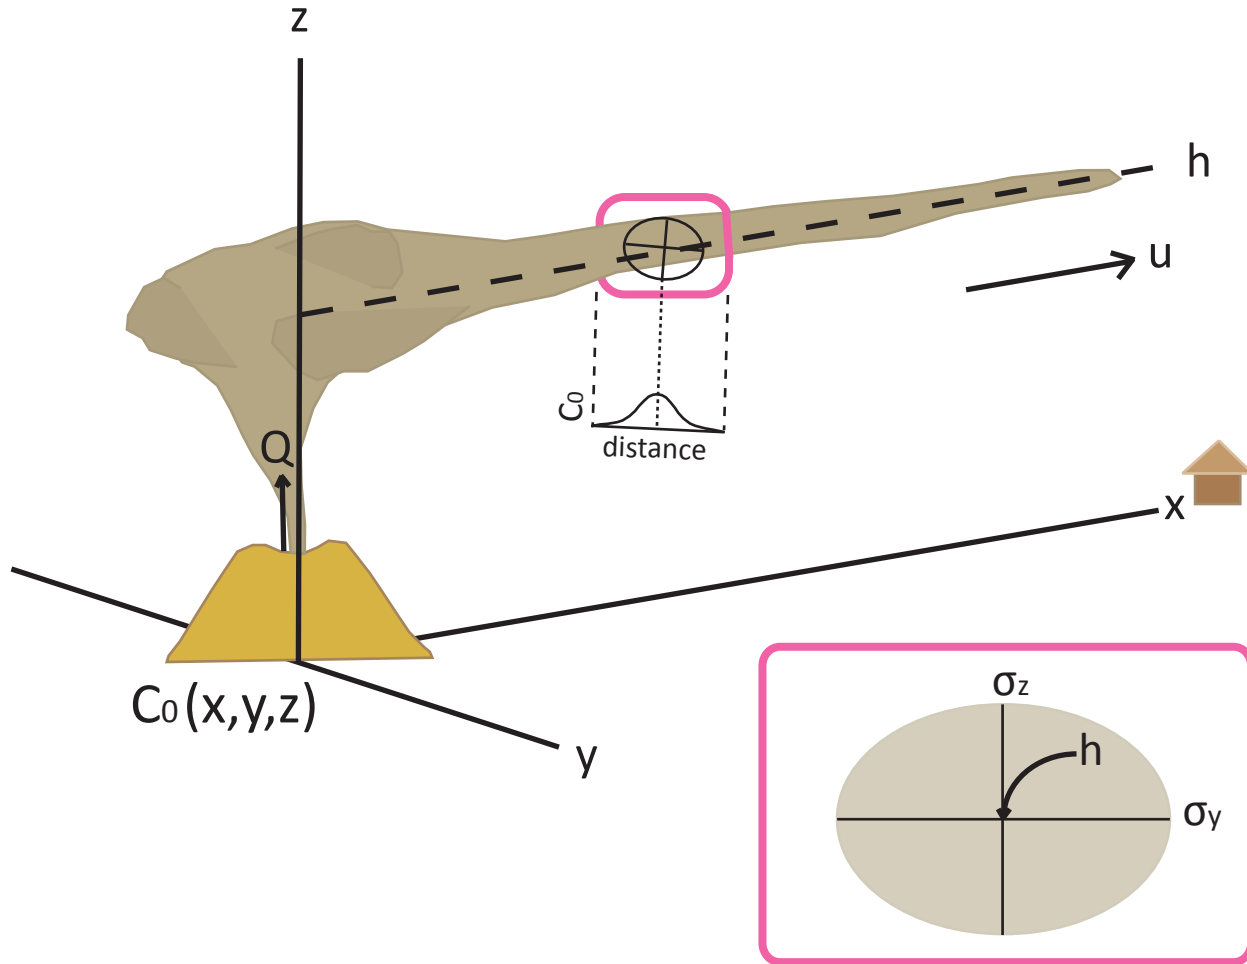

Figure 9: Schematic of the point source Gaussian plume model implemented for cinder cone eruptions to predict volatile concentrations downwind from the vent. The model assumes a Gaussian distribution of volatile concentration within the plume and assumes the plume reaches a steady state. The variables in the model includes: (x) downwind spreading distance; (y) horizontal spreading distance; (z) vertical spreading distance; (C_0) initial volatile concentration in the parental melt; (Q) magmatic flux; (h) centerline height of the plume; (u) wind speed; (σ_z) cross-sectional concentration in the vertical spreading direction; (σ_y) cross-sectional concentration in the horizontal spreading direction.

magmatic MER of 10^4 kg/s as it is the average MER for Violent Strombolian cinder cone eruptions found by Pioli et al. (2009). A wind speed of 9 mph (0.004 km/s) was estimated for the annual average wind speed in the central Oregon Cascades from historical databases, and I used an average plume centerline height of 1.5 m. σ_z and σ_y are the cross-sectional concentrations of a gas within the plume in the vertical and horizontal directions, respectively. σ_z and σ_y are defined by the stability of the plume and are calculated by:

$$\sigma_y = 465.11628x(\tan\theta) \quad (8)$$

where,

$$\theta = 0.017453293(c - d\ln(x)) \quad (9)$$

and,

$$\sigma_z = ax^b \quad (10)$$

The variables a, b, c, and d are assigned values that are a function of plume stability and x, the downwind distance (Appendix E). The stability of the plume can be described as “unstable”, “slightly stable”, “moderately stable”, “neutral”, “slightly stable”, or “stable” (Hanna et al., 1981). The stability of the plume is defined by its shape (or its vertical response), which is a function of atmospheric stability. After assessment of historic mafic eruption plumes of similar eruption styles (e.g. Parícutin, Cerro Negro, Etna; Figure 10) and descriptions of plume stability from Hanna et al. (1981), Guenther (2010), and EPA (2012), I chose a plume stability rating from “unstable” to “neutral” to assess volatile concentration within the plume downwind of the vent for a range of plume behavior.

Figure 10: Examples of unstable plume stability in historic eruptions of Paricutin (top) and Cerro Negro (bottom).

CHAPTER V

RESULTS

5.1. Melt inclusion compositions

The K_2O , SiO_2 , TiO_2 , S, Cl, and F concentrations for olivine-hosted melt inclusions and matrix glass analyzed in this study are listed in Tables 3 and 4. The concentrations of these elements (except for F) in the melt inclusions analyzed in this study are similar to the measured compositions reported by Ruscitto (2011), Rasmussen (unpublished), and Walowski (unpublished) for the same cones. Melt inclusions from the central Oregon and northern California Cascades trapped mostly basalt (45-53 wt% SiO_2) to basaltic-andesite (53-57 wt% SiO_2) melt compositions: Collier Cone (51.5-56.1 wt% SiO_2); Yapoah Crater (49.9-53.3 wt% SiO_2); Four-In-One Fissure (51.4-55.1 wt% SiO_2); Garrison Butte (47.4-51.0 wt% SiO_2); Cinder Cone (50.9-60.6 wt% SiO_2); BORG (49.9-53.4 wt% SiO_2); BAS44 (49.0-50.5 wt% SiO_2). Melt inclusions from these cinder cones are medium-K calc-alkaline in composition, but the melt inclusions with the highest SiO_2 contents from Cinder Cone extend into the high-K field (Figure 11). BAS44 displays a transition to a LKT type magma, a signature distinguished by low (<0.5 wt%) K_2O and a high (>2.2) TiO_2/K_2O ratio (Leeman et al., 2005). BORG and Garrison Butte also display a slight transition into a LKT type magma, yet Garrison Butte has slightly elevated K_2O (0.33-0.87 wt%) and BORG has a slightly lower TiO_2/K_2O ratio (1.37-.2.28) in comparison to BAS44. Interestingly, Garrison Butte, BORG, and BAS44 lie ~10 km farther east of the Cascadia trench than Collier Cone, Yapoah Crater, Four-In-One Fissure, and Cinder Cone. Collier Cone, Yapoah Crater, Four-In-One Fissure, and

Table 3: Major and minor element concentrations for melt inclusions of cinder cones from the central Oregon Cascades and northern California; in wt%. Major and minor elements not analyzed in this study (*italic*) are provided by Ruscitto (2011) (OR), Walowski et al. (unpublished) (CA); and Rasmussen et al., (unpublished) (CA)

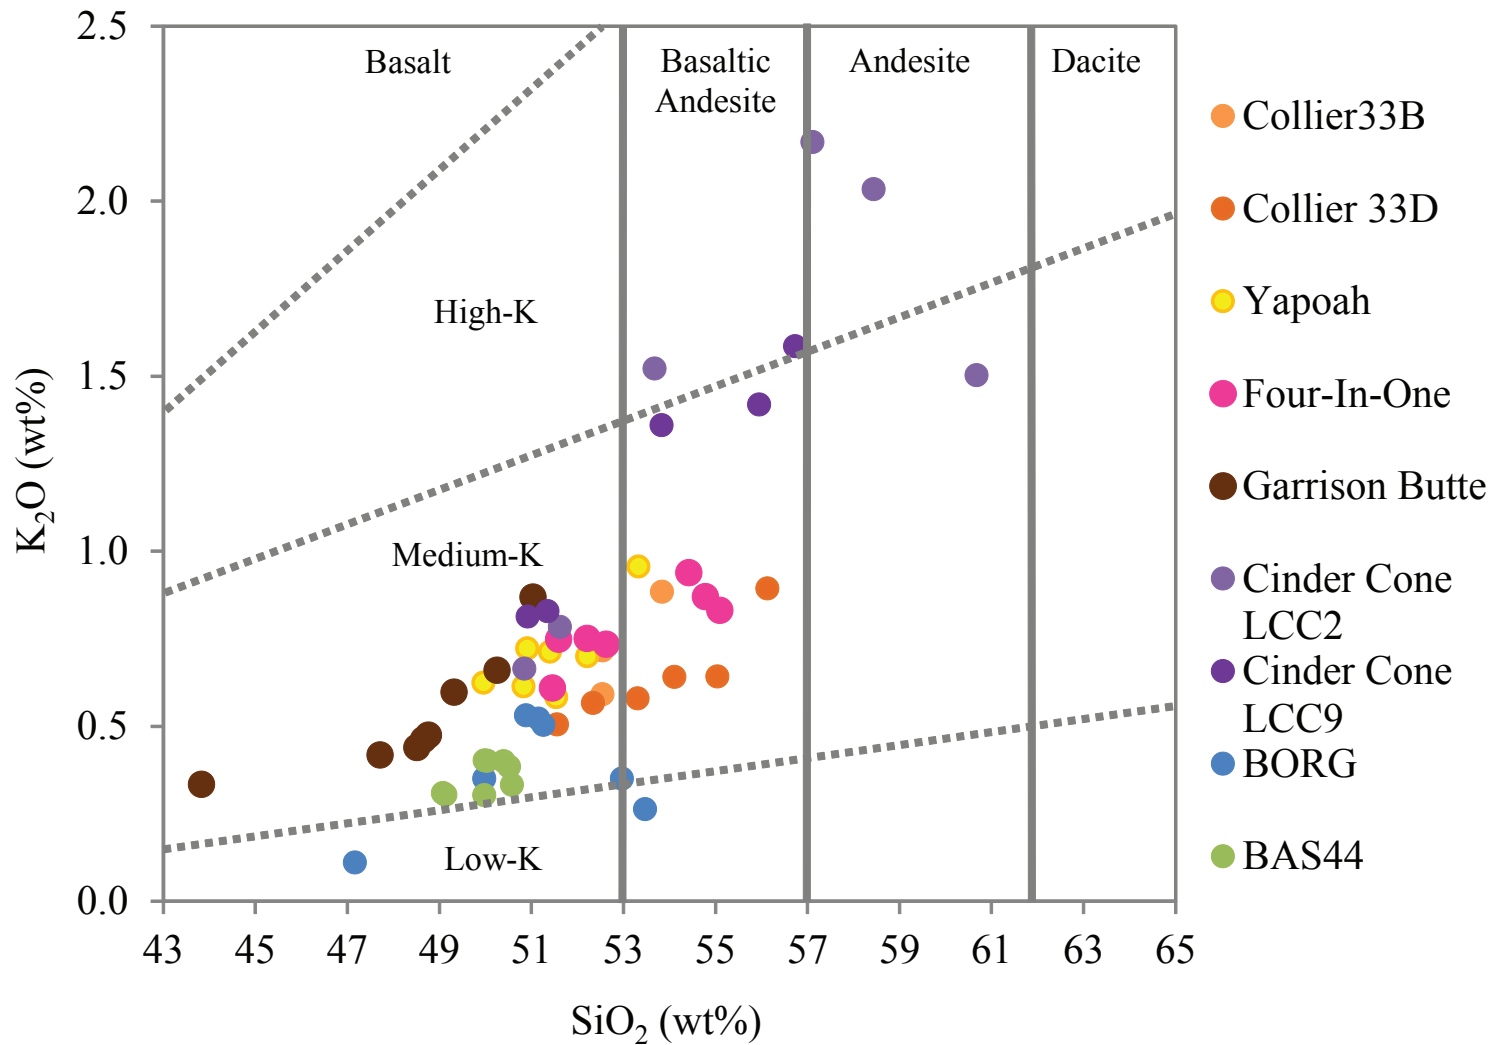

Figure 11: Melt inclusion K_2O and SiO_2 concentrations. Most central and southern Cascades melt inclusions plot in the medium-K basalt and basaltic andesite fields. Garrison Butte, BORG, and BAS44 inclusions are slightly less alkalic, with lower SiO_2 concentrations. Contaminated melt inclusions from Cinder Cone plot in basaltic andesite to andesite fields and contain higher K_2O contents.

Cinder Cone all display typical subduction zone chemical characteristics (calc-alkaline basalt, or CAB) signatures, with elevated (>0.6-2.2 wt%) K₂O. See Table 5 for a summary on central and southern Cascades magma compositions.

5.2. Tephra bulk compositions

Tephra erupted from central Oregon and northern California cinder cones is mostly basaltic andesite to andesitic (54-62 wt% SiO₂) in composition – Collier Cone (61.7-62.7 wt% SiO₂); Yapoah Crater (61.3-61.5 wt% SiO₂); Four-In-One Fissure (57.7-58.1 wt% SiO₂); Garrison Butte (52.8-58.5 wt% SiO₂); Cinder Cone (60.1-62.7 wt% SiO₂); BORG (57.3-59.0 wt% SiO₂); BAS44 (53.0-53.5 wt% SiO₂).

5.3. Dissolved volatiles

Sulfur contents in the melt inclusions are highly variable, ranging from below detection (50 ppm) to a maximum of 1750 ppm at BORG. However, most melt inclusions contain >700 ppm S. The highest concentrations of S occur in the melt inclusions that have compositions transitional to LKT. The concentrations of chlorine range from 240 to 1350 ppm, with the lowest Cl concentrations found in melt inclusions from BAS44. The Cl contents found in melt inclusions from Yapoah Crater plot well above Cl concentrations of the other central and southern Cascades cones. Measured fluorine contents range from below detection (90 ppm) to 380 ppm. No systematic difference in F between the LKT transitional and CAB magma types is distinguishable.

The matrix glass from all cones has low concentrations of S compared to the melt inclusions, in contrast to the data for Cl and F (Table 4; Figure 12). Measured S contents

range from below detection (50 ppm) to 450 ppm, with the majority of data points hovering near the detection limit. Chlorine concentrations remain constant from melt inclusions to tephra matrix glass, with the minimum and maximum concentrations being 260 ppm and 1040 ppm, respectively. Fluorine contents also remain constant within the melt, ranging in concentration from 115-385 ppm.

Figure 12: Dissolved volatile contents in olivine-hosted melt inclusions (filled circles) and matrix glass (open diamonds). Sulfur evolution is dominated by degassing, where Cl and F evolution is predominately dominated by a moderate degree of crystallization with degassing.

CHAPTER VI

DISCUSSION

6.1. Melt evolution- The importance of fractional crystallization and crustal assimilation during ascent

Systematic variations of incompatible element concentrations (K_2O , TiO_2) in the melt inclusions and matrix glass define distinct trends that are generated by similar melt evolution processes. Melt components not incorporated into crystallizing minerals become increasingly concentrated in the residual melt as crystallization proceeds and are referred to as “incompatible”. K_2O and TiO_2 are commonly used as an index of fractional crystallization in mafic melts because both behave systematically with crystallization of mafic minerals. K_2O is not incorporated into the structure of crystallizing mafic minerals (i.e., olivine, plagioclase, spinel, pyroxene). The covariance of K_2O and TiO_2 that is commonly seen in many data suites of cinder cone magmas suggests there has not been substantial crystallization of titanomagnetite (Erlund et al., 2010; Johnson et al., 2010). K_2O and TiO_2 can also be used as an index of crustal assimilation in mafic magmas. Crustal materials are enriched in K_2O , therefore increasing the concentration of K_2O during assimilation. TiO_2 however, will decrease in concentration with the addition of a crustal contaminant because granitic and silicic volcanic rocks generally have very low TiO_2 contents (Erlund et al., 2010).

Crystallization via Rayleigh fractionation, or the removal and separation of minerals from a melt, is identified by a linear trend of incompatible element concentrations (e.g. K_2O , TiO_2) along a fractionation line (Figures 13, 14). Assimilation

of more silicic material, such as the proposed granitic country rock adjacent to Lassen Peak, can be identified using a diagram of $\text{TiO}_2/\text{K}_2\text{O}$ vs. SiO_2 (Figures 15, 16). If data points lie along a hyperbolic mixing line between a primitive magma composition and a more evolved crustal contaminant, the magma is interpreted to be contaminated. Figures 13 and 14 show the effects of fractional crystallization, both with and without assimilation. The data for the crustal contaminant used in these figures, as well as for the mixing curves in Figures 15 and 16 come from Table 2. Based on melt inclusion and matrix glass data variations, only a few of the magmas experienced pure fractional crystallization as they ascended from the lower crust. Instead, each parental magma has experienced a combination of crystal fractionation and crustal assimilation from the lower crust to the surface. Figures 17 and 18 show a comparison among all cones of the effects of fractional crystallization and crustal assimilation, respectively.

The spread in melt inclusion data points from Yapoah Crater and Garrison Butte can be explained by a magmatic history of pure fractional crystallization (Figure 13). Yapoah Crater magma fractionated up to 36% crystals. The parent magma at Garrison Butte fractionated up to 28% crystals. The melt inclusion recording the lowest K_2O and TiO_2 concentrations at Garrison Butte is conceivably a xenocryst as fractionation lines emanating from this melt inclusion do not describe the evolution of the other inclusions. It is also possible that the spread in melt inclusion data represents the simultaneous evolution of two similar, but compositionally distinct magmas. Work by Strong and Wolff (2003) in the southern segment of the Cascades suggests scoria cones can tap magmas from different mantle sources as melts can travel through the crust without storage within a magma chamber or because of inefficient mixing within a magma

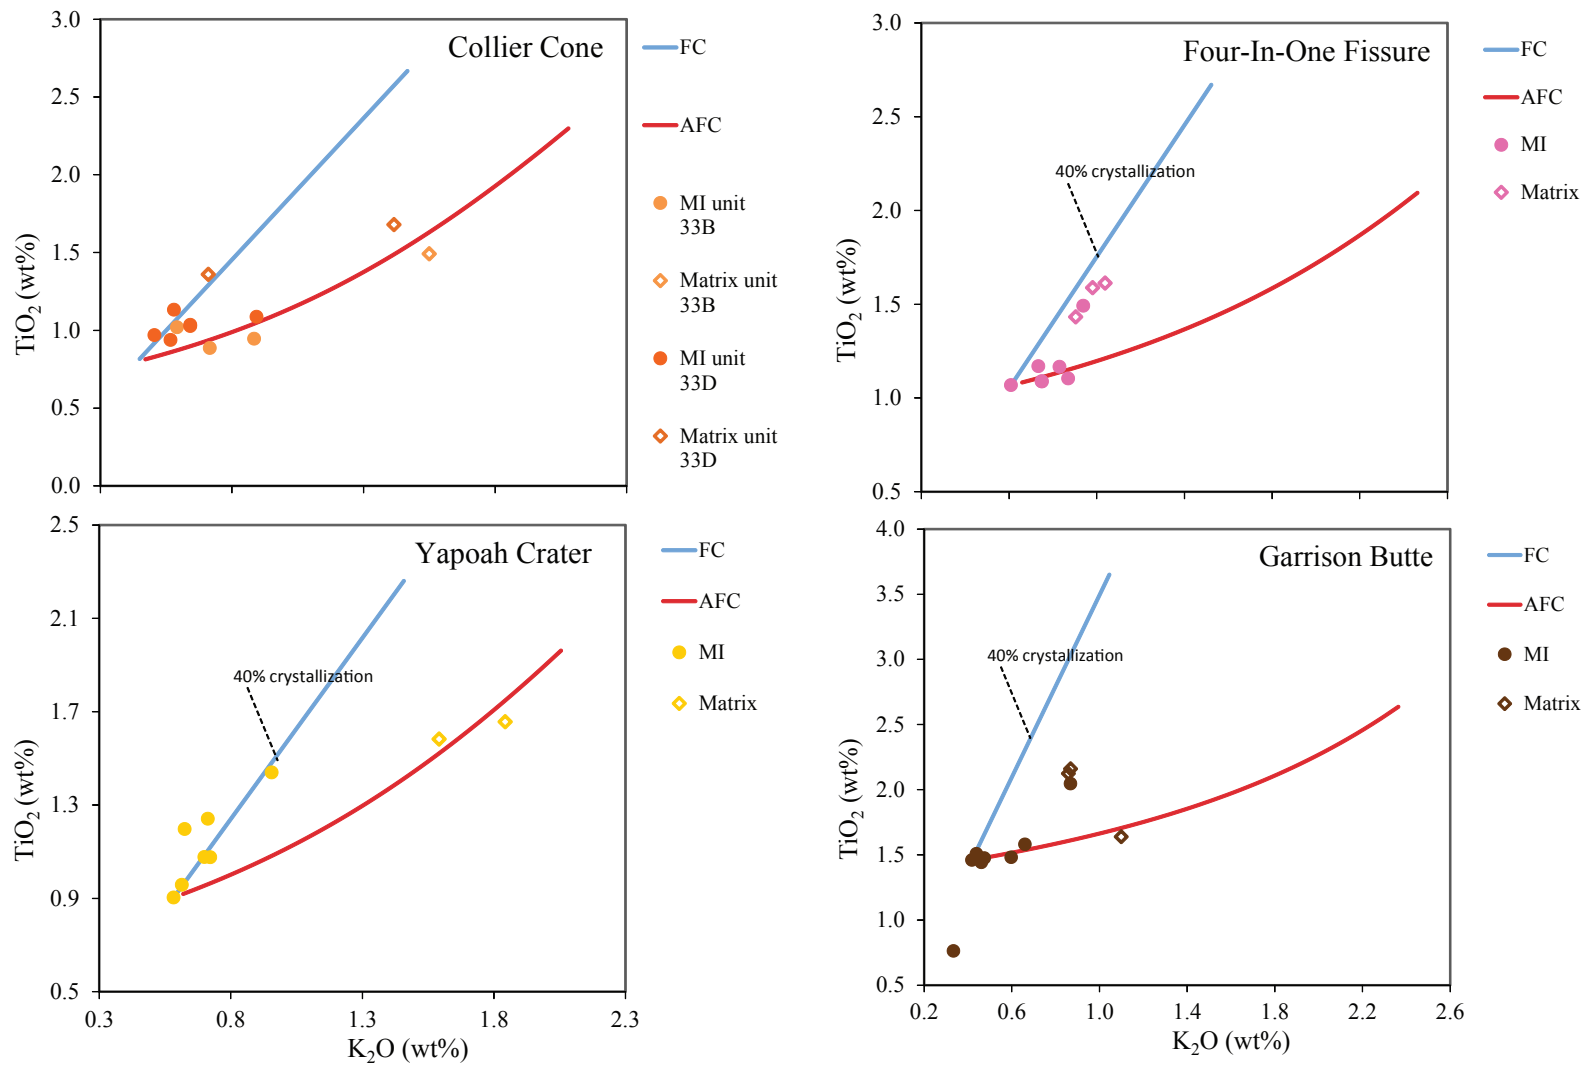

Figure 13: Evolution of the melt through crystal fractionation and crustal assimilation recorded by olivine-hosted melt inclusions (filled circles) and matrix glass (open diamonds) in central Oregon. The lowest K_2O and TiO_2 concentration melt inclusion was chosen as the best representative of the parental magma composition. Melt inclusions from Collier Cone do not represent the most primitive melt and therefore a hypothetical parent melt was used to calculate crystal fractionation and assimilation. FC denotes pure fractionation of crystals; AFC denotes crystal fractionation with assimilation.

Figure 14: Evolution of the melt through crystal fractionation and crustal assimilation recorded by olivine-hosted melt inclusions (filled circles) and matrix glass (open diamonds) in northern California. The lowest K_2O and TiO_2 concentration melt inclusion was chosen as the best representative of the parental magma composition. FC denotes pure fractionation of crystals; AFC denotes crystal fractionation with assimilation.

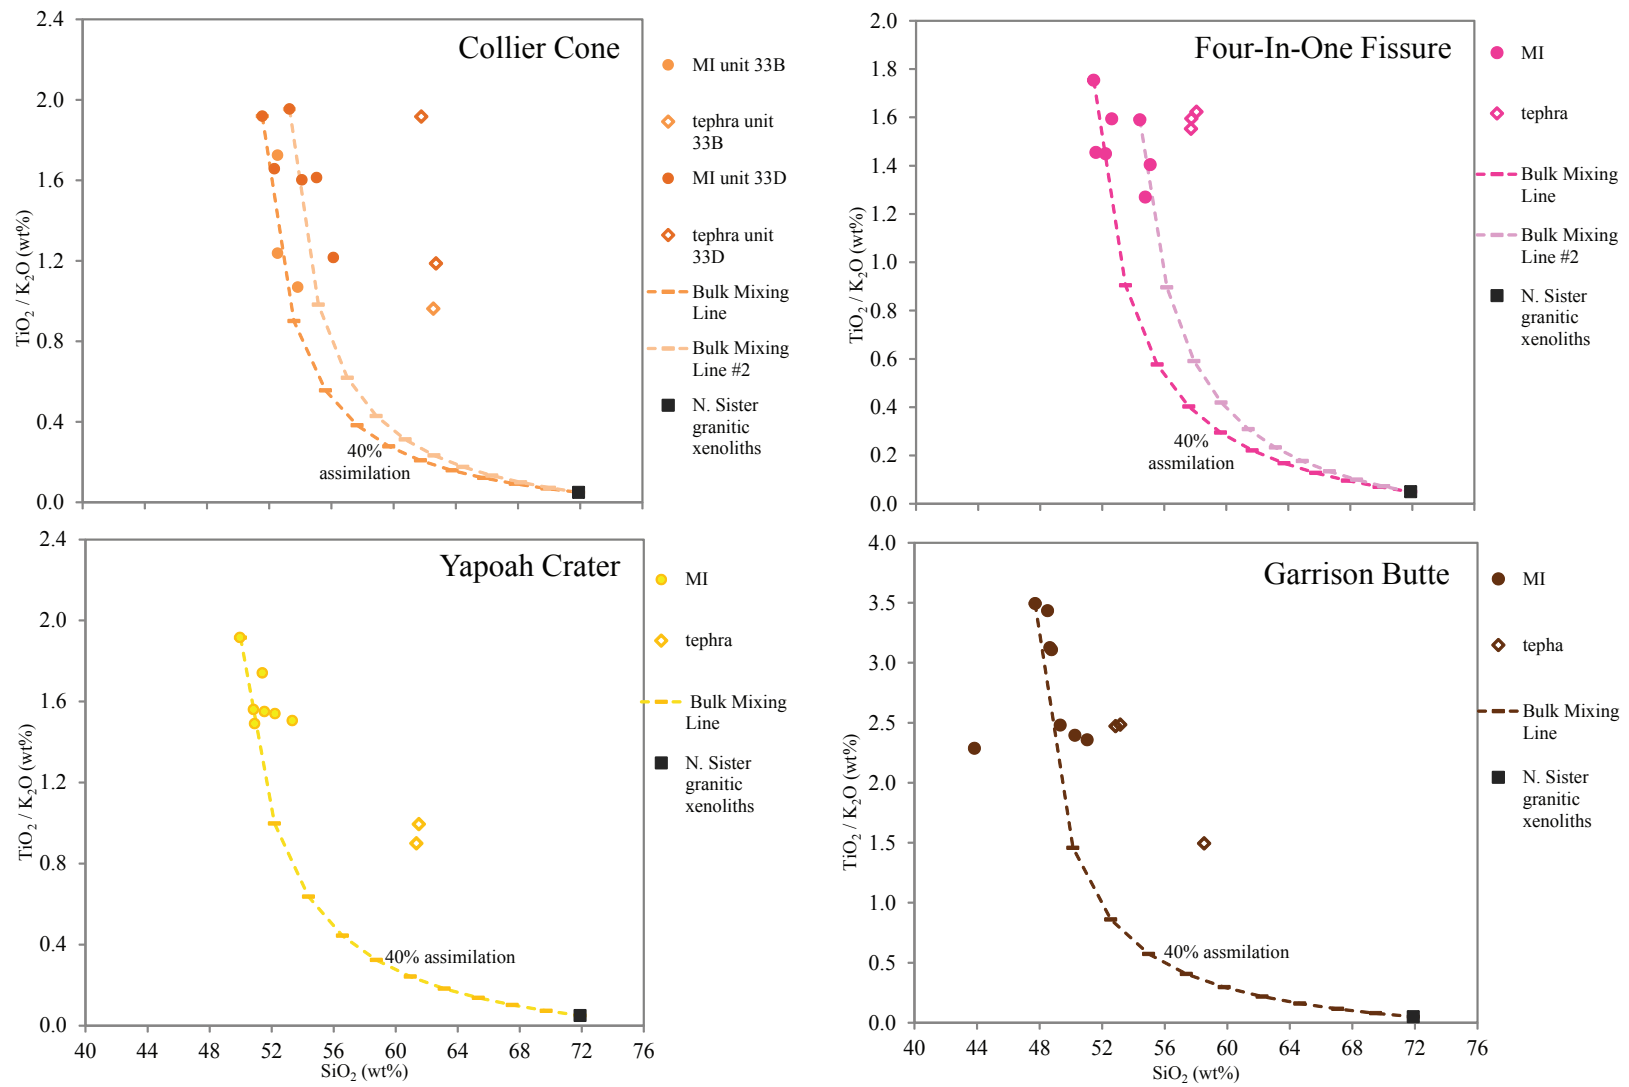

Figure 15: Individual TiO_2/K_2O and SiO_2 contents of olivine-hosted melt inclusions (filled circles) and matrix glass (open diamonds) for the central Oregon Cascades cinder cones.

Figure 16: Individual TiO_2/K_2O and SiO_2 contents of olivine-hosted melt inclusions (filled circles) and matrix glass (open diamonds) for northern California cinder cones.

chamber. Starting from a magma that is represented by the lowest K_2O inclusion, the matrix glass from Yapoah Crater suggests the magma fractionated up to 52% crystals with as much as 13% assimilation of silicic material similar to the granitic xenoliths erupted by Collier Cone. The spread of matrix glass data points from Garrison Butte can be explained by end-member models requiring 32% fractional crystallization or fractionation up to 22% with as much as 4% silicic assimilation.

Cinder Cone is the only cone to show fractionation with a high percentage of crustal assimilation in both the melt inclusions and the matrix glasses (Figure 14). Using the melt inclusion with the lowest K_2O content the range of values recorded by melt inclusions can be explained by fractionation of up to 44% crystals with as much as 37% assimilation of a silicic contaminant like that of granitic country rock near Lassen Peak. Matrix glass compositions require up to 50% crystals with as much as 43% silicic assimilation from a magma represented by the lowest K_2O concentrations.

The melt inclusions from Collier Cone, Four-In-One Fissure, BORG, and BAS44 record the evolution of magma that can either be explained by crystal fractionation or crustal assimilation (Figures 13, 14). I suggest the melt inclusions of Collier Cone show entrapment of an evolved melt such that the actual parent magma of Collier Cone is composed of lower K_2O and TiO_2 concentrations than those shown by the melt inclusions. Using this hypothesized parent magma, magma from Collier Cone fractionated up to 28% crystals or fractionated up to 28% of crystals with as much as 6% assimilation with the granitic xenoliths. Four-in-One Fissure magma fractionated up to 28% crystals or fractionated up to 10% crystals with as much as 4% silicic assimilation. Melt inclusions from BORG show that the magma fractionated up to 18% crystals or

Figure 17: TiO₂ and K₂O contents of melt inclusions (filled circles) and matrix glass (open diamonds) from central Oregon and northern California. Melt inclusions show evolution by crystal fractionation with coupled assimilation. Yapoah Crater shows significant fractionation, with tephra appearing to assimilate with a granitic-like body. TiO₂ and K₂O diagrams for individual cones are found in Figures 13 and 14.

Figure 18: $\text{TiO}_2/\text{K}_2\text{O}$ and SiO_2 contents of melt inclusions (filled circles) and matrix glass (open diamonds) from central Oregon and northern California. The majority of the melt inclusions follow an assimilation path toward a depleted granitic contaminant, most notably melt inclusions from Cinder Cone. $\text{TiO}_2/\text{K}_2\text{O}$ vs. SiO_2 diagrams for individual cones are found in Figures 15 and 16.

fractionated up to 28% with as much as 6% silicic assimilation. At BAS44, the magma fractionated up to 12% crystals or fractionated up to 12% crystals with as much as 1% assimilation of a silicic contaminant like that of granitic country rock near Lassen Peak. The evolution in the matrix glass of these four cinder cones varies. Four-in-One Fissure records fractionation only of the melt (up to 32% crystals), BAS44 matrix glass record up to 32% crystal fractionation with as much as 4% silicic assimilation, and matrix glasses of Collier Cone and BORG magmas can be explained by either fractionation up to 40% and 62% crystals, respectively or fractionation up to 54% and 66% crystals with as much as 12% and 14% silicic assimilation, respectively.

6.2. Volatile evolution and degassing

When a melt fractionates, the concentration of incompatible elements will increase. Volatile elements can also behave incompatibly if they have relatively high solubility and are not entering other solid or immiscible liquid phases (e.g., sulfide minerals). Melting of an assimilant can also increase or decrease the concentration of highly soluble elements, such as S, Cl, and F, in the melt, depending on the volatile content of the assimilant. The controls of fractional crystallization or crustal assimilation on dissolved volatiles vary with each cinder cone. Some cones are more affected by fractional crystallization whereas others are more affected by crustal assimilation. Figure 19 shows the controls on S, Cl, and F evolution. A decrease in volatile concentration with an increase in K_2O can be attributed to partial degassing or interaction with a contaminant that contains a very low concentration of the volatile. Where assimilation is minimal, Cl concentrations follow along a crystal fractionation line. Yapoah Crater

Figure 19: Volatile/K₂O and TiO₂ contents of olivine-hosted melt inclusions (filled circles) and matrix glass (open diamonds) for central Oregon and northern California cinder cones. As incompatible elements (K₂O, TiO₂) increase, volatile concentrations decrease strongly through degassing, decrease moderately through simultaneous crystallization and degassing, or display concentrations similar to the most primitive melts.

displays a typical fractional crystallization trend. Chlorine increases with K_2O as the melt fractionates 36% crystals. Melt inclusions of BAS44 collapse onto a fractional crystallization line as Cl increases with 12% crystallization. Fluorine should also follow a fractionation line as it is an element with high melt solubility. In general, F appears to increase at a faster rate than K_2O . However, given the relatively large uncertainties on the F measurements, I conclude that F increases at the same rate as K_2O , consistent with fractional crystallization. Detection of S evolution within each melt is more difficult due to sulfur's strong ability to exsolve into a vapor phase and degas from the system at lower pressures. Controls on S evolution in the melt inclusions and matrix glass at all cones are masked by strong degassing and therefore are not discernable. Averages of major, minor, and volatile concentrations for each cone can be found in Figures 20 and 21.

No volatile analyses have been performed on the silicic xenoliths near North Sister or Lassen Peak, so to account for effects on volatile concentration due to assimilation, I used upper crustal compositions of S, Cl, and F compiled by Hartman and Wedepohl (1993), Wedepohl (1995), and Rudnick and Gao (2003). By using upper crustal averages I calculated the original S, Cl, and F concentrations in the magma with varying degrees of fractional crystallization and assimilation before any degassing had occurred. By assuming a non-zero volatile concentration in the silicic contaminants near North Sister and Lassen Peak I can make a reliable estimate of volatile evolution within the melt and the quantity of gas released during eruption.

Figure 20: Averaged volatile and K_2O concentrations for cinder cones in the central and southern Cascades. Error bars represent 2 standard deviations. Filled circles represent averaged olivine-hosted melt inclusions; open circles represent averaged matrix glass. Cinder Cone melt inclusions were separated into 3 distinct groups based on their K_2O content. An average was created for each grouping.

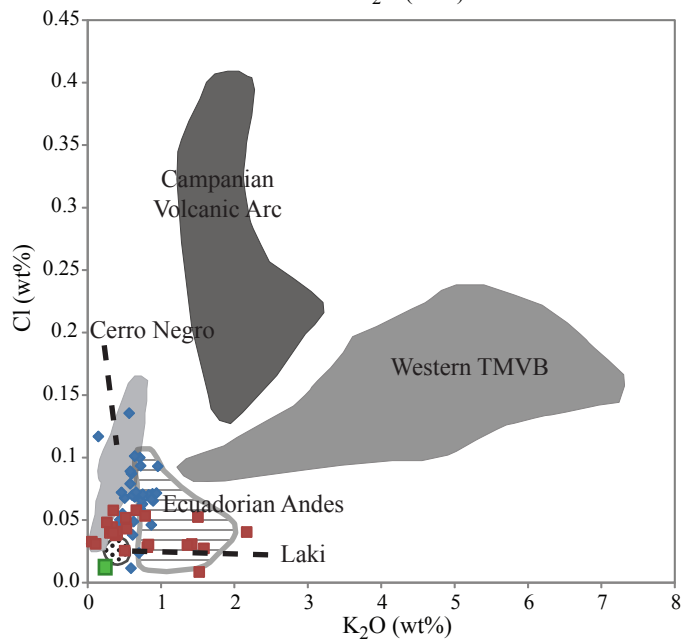

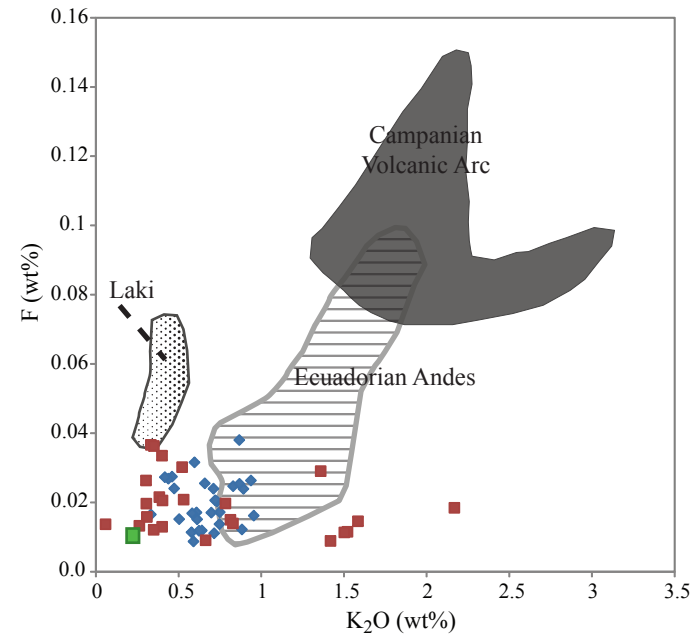

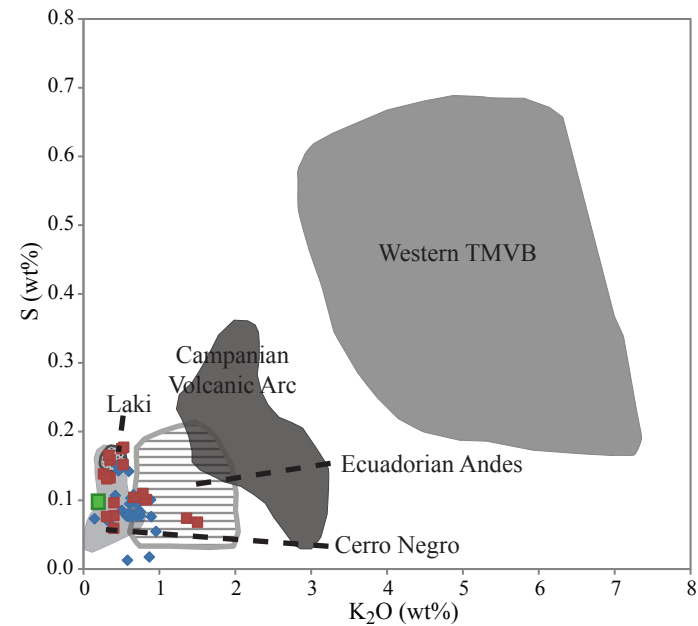

Figure 21: Averaged TiO₂, K₂O, and SiO₂ concentrations for cinder cones in the central and southern Cascades. Error bars represent 2 standard deviations. Filled circles represent averaged olivine-hosted melt inclusions; open circles represent averaged tephra groundmass glass. Cinder Cone melt inclusions were separated into 3 distinct groups based on their K₂O content. An average was created for each grouping. Legend for symbol colors is the same as in Figure 24.

6.3. Comparison of volatile concentrations in Cascades magmas to other global mafic eruptions

Mid-ocean ridge basalts have S, Cl, and F values on average of ~1000 ppm, ~100 ppm, and ~140 ppm, respectively (Jambon, 1994; Wallace, 2005). Values for S, Cl, and F concentrations in mafic arc magmas are higher in comparison to MORB because of fluid fluxing from the subducted slab into the mantle wedge (Wallace, 2005; Ruscitto, 2011). Evolved melts contain low concentrations (≤ 200 ppm) of S due to sulfur's strong preference to partition into a vapor phase or precipitate in sulfide or sulfate minerals, such as anhydrite, during crustal storage (Wallace and Anderson, 2000; Wallace, 2003; Wallace and Edmonds, 2011). The incompatibility of Cl and F at high pressure causes their concentrations to increase in the melt with increasing differentiation, in contrast to S (Metrich and Wallace, 2008). Chlorine concentrations can reach up to 2000 ppm in silicic magmas with the addition of NaCl-rich fluid, such as seawater, or a Cl-rich vapor (Wallace, 2005; Metrich and Wallace, 2008). Volcanic locales such as Etna, Arenal, and Ruapehu record F levels over 1000 ppm (Cronin et al., 2003; Spilliaert et al., 2006; Wade et al., 2006).

Volatile concentrations in magmas erupted from central Oregon and northern California are elevated above MORB values and are comparable to mafic magmas from other volcanic arcs (Wallace, 2005). Most notably, volatile contents of central Oregon and northern California have considerable overlap with eruptive centers such as Cerro Negro (Roggensack et al., 1997; Portnyagin et al., 2012) (Figure 22). Volatile concentrations at Etna, La Sommata, and at the highly potassic cones in the Trans-Mexican Volcanic Belt (TMVB) are significantly elevated above the volatile contents of

- ◆ Oregon Cascades
- Northern California
- N-MORB

Figure 22: Comparison of Cascades arc volatile contents to other global arc volatile contents. Filled in areas represent melt inclusion values for the Campanian Arc (La Sommata, Mt. Etna; dark grey), the Western Trans-Mexican Volcanic Belt (medium grey), Cerro Negro (light grey), the Ecuadorian Andes (stippled), and Laki (speckled). Melt inclusions from the central Oregon Cascades and northern California have significant overlap with volatile concentrations from Cerro Negro and Laki. MORB data from Jambon, 1994; Wallace, 2005. Global data from Thordarson et al., 1996; Le Voyer et al., 2008; Vigouroux et al., 2008; Le Voyer, 2009; Portnyagin et al., 2012.

the Cascades cones, indicating a dissimilar magmatic source and magmatic evolution. Vigouroux et al. (2008) suggested that the highly potassic magmas erupted in the TMVB involved melting of a metasomatized phlogopite-apatite-rich mantle source. Interestingly, with the exception of F (of which no F melt inclusion data currently exists in publication for Cerro Negro), S and Cl concentrations match well with those of Cerro Negro. Much work has documented the hazards associated with historical eruptions at Cerro Negro and the dangers they have presented for human populations and ecosystems (McKnight and Williams, 1997; Hill and Connor, 1998; Connor, 2001). The upper limits of volatile concentrations in the central and southern Cascades also match well with the 1783-1784 fissure eruption at Laki. The eruption at Laki is a significant event in volcanic history because it became known as one of the greatest atmospheric pollutants in prehistoric and historic records. Thordarson et al. (1996) calculated a release of 75% of the dissolved volatiles over the entire eruption. Such large degassing events affect both atmospheric and ground/surface water chemistry. Granted, the sheer eruptive volume of the Laki eruption (~0.5-2.0 km³ for each eruptive episode, 15.1 km³ total; Thordarson et al., 1996) sets it apart from the Cascades, but it is important to note as a possible eruptive outcome for central Oregon and northern California.

6.4. Release of SO₂, HCl, and HF into the troposphere

Volatile exsolution is a critical driving force for volcanic eruptions as the expansion of bubbles accelerates magmatic froth upward through the conduit, eventually causing it to exit the vent as a gas-rich jet (Parfitt and Wilson, 1995). When the vesicularity reaches ~75% by volume, fragmentation occurs (Cashman et al., 2000).

Volatiles also control the eruption style exhibited by a cinder cone through a dependence on the regime of gas bubble transfer (e.g. Belien, 2011) and the magma supply and ascent rates (e.g. Pioli et al., 2008). It has been documented that high volatile fluxes can sustain lava fountains and play a major role in the transition from an effusive eruption into a Strombolian-type eruption (Wallace and Anderson, 2000).

Following the methods outlined in Chapter IV for calculating the masses of volatiles released into the troposphere during the explosive phase of an eruption, I estimate volatile emissions for SO₂, HCl, and HF (Table 6) using calculated melt inclusion values representative of the melt at time of eruption following fractional crystallization with some assimilation (c_{adj}) and their corresponding matrix glass compositions. An example of this procedure can be seen in Figure 23, where data from Yapoah Crater reveals a minimum and maximum of degassing from the calculated evolved melt. Examples for the remaining six cones can be found in Appendix F. Given the relatively elevated oxygen fugacities of the magmas involved (Ruscitto et al., 2010), I assume that all S was released as SO₂ (e.g. Wallace and Carmichael, 1994), though it is possible that some H₂S was also involved. Based on the low concentrations of S in the matrix glass samples, it appears that nearly all the dissolved S was released during eruption. Cinder Cone released the largest mass of SO₂, but all cones released 88-100% of their initial S content. Collier Cone, Yapoah Crater, and Cinder Cone released 31-49% of their initial Cl in the form of HCl, whereas Four-In-One Fissure, BORG, and BAS44 lost 14-32% Cl. Garrison Butte efficiently retained Cl and lost only 0-10% of its initial Cl concentration. Like Chlorine, moderate F was degased during eruption. Yapoah Crater, Garrison Butte, Cinder Cone, and BAS44 lost 6-50% of the initial F

Figure 23: An example of volatile evolution and degassing from Yapoah Crater. The melt inclusion with the lowest TiO_2 and K_2O concentration was used to calculate the percent fractional crystallization and assimilation of the magma. Using these values, a volatile concentration of the evolved melt was calculated. This calculated evolved melt concentration represents the melt prior to degassing and is used to assess the total amount of S, Cl, and F released during eruption.

concentrations as HF. Matrix glass compositions do show however, that F is more soluble in the melt than Cl, as many cones had matrix glass compositions that showed no degassing at all. Collier Cone lost 0-50% F, Four-in-One Fissure lost 0-5% F, and BORG experienced no degassing of F.

The volatiles Cl and F have very high solubility in mafic melts and thus behave as incompatible elements during fractional crystallization. Even at near surface pressures F remains quite soluble, but Cl can begin to partition into the vapor phase at low pressures as large amounts of H₂O and CO₂ begin to exsolve (Metrich and Wallace, 2008). Dissolved CO₂ and H₂O will exsolve into the vapor phase relatively early and become completely separated from the melt. This can cause S, Cl, and sometimes F to diffuse into the exsolved bubbles as pressure within the conduit decreases. These vapors can then readily escape from the magma during eruption or passive degassing through bubble coalescence and bubble rise or through the permeable flow of gas through pathways within a magmatic foam or crystal-rich magma (Belien, 2011; Pioli et al., 2012). Sulfur, in contrast to Cl and F, is somewhat less soluble and can begin to partially partition into a vapor phase at middle to upper crustal pressures (4.5- <1 km) (Wallace, 2005; Metrich and Wallace, 2008). Thus, sulfur shows more degassing at near surface pressures.

It is important to note that because cinder cone systems are characterized by polybaric crystallization, i.e. crystallization at multiple pressures, variable degassing of the melt may have occurred before melt inclusions were formed. Even though I use a calculated melt inclusion representative of an evolved melt that has experienced no degassing, the volatile concentrations captured by the olivine-hosted melt inclusions may not have recorded the initial concentration of the less soluble volatiles, as they degas

readily at lower pressures. Olivine-hosted melt inclusions may also reflect lower concentrations of the higher solubility volatiles if crystallization occurred at very low pressures (Metrich, 1990; Metrich and Wallace, 2008).

Using the modified Thordarson et al. (1996) method to calculate the total volatile species mass released during eruption, I show that each cone released between 0.05 to 4.5 Mt of SO₂, 9.9×10^{-4} to 0.2 Mt of HCl, and 9.3×10^{-5} to 0.2 Mt of HF (Table 6). Even though the CAB lavas and the transitional LKT lavas share similar concentrations of S, Cl, and F, the eruptive volumes of the cones drastically influence the mass of volatile species released from the vent. Cinder Cone has the highest predicted mass of volatiles released because the eruption volume of Cinder Cone was by far the largest (0.29 kg/km^3) compared to other cones analyzed in central Oregon and northern California. It is important to note that I focus on the degassing of volatiles at the vent; however additional dissolved volatiles can be lost from lava flows during transport and cooling.

Significant degassing of Cl and F occurs passively as lava is extruded from the base of the cone because increased crystallization of the flow decreases the amount of melt that contains the dissolved volatiles. Fluorine is very soluble at atmospheric pressures (~1 atm) and can remain dissolved in the lava flow. However, no F can remain dissolved in a lava flow that is 100% crystalline. Therefore during transport, F and other high melt soluble volatiles like Cl should degas as the lava cools and crystallizes. Documented gaseous fogs emanating from degassing Hawaiian lava flows as they reach the ocean have been shown to be harmful to nearby residents (e.g. Heliker et al., 2003). I attempted to analyze glassy matrix within lava samples from each respective cone to understand the possible risk to nearby communities. Petrographic slides were assembled

from lava samples collected in the field, however, after observation of the thin sections under a petrographic microscope it was determined that only the lava flow sample from Cinder Cone had a sufficient percentage of glassy matrix to analyze with the Cameca SX100 electron microprobe. The lava sample was analyzed under the same conditions previously presented for olivine-hosted melt inclusions and matrix glass (major and minor element compositions can be found in Appendix D). The data shows considerable loss of S during emplacement and moderate losses of Cl and F (Figure 24). Applying the degassing calculations outlined in Chapter IV to the lava matrix glass yields degassing percentages of SO₂ (99%), HCl (51%), and HF (28-44%) from a calculated melt inclusion that represents the concentration in the magma before the lava was erupted to the surface. These degassing percentages equate to a release of 7.49 Mt SO₂, 0.31 Mt HCl, and 0.16-0.25 Mt HF during effusive eruption activity.

A similarly designed experiment by Thordarson et al. (1996) on the 1783-1784 AD fissure eruption of Laki estimated that ~25 Mt SO₂ (~20%), ~3 Mt HCl (~25%), and ~7 Mt F (~25%) were liberated during and after lava emplacement and crystallization. The Laki fissure eruption is considered to be one the greatest atmospheric pollution events as the eruption released a combined 110 Mt of SO₂, HCl, and HF during its year-long eruptive episode. Though Cinder Cone released a much greater percentage of gas during its eruption compared to Laki, its relatively small eruption volume constrains the total potential amount of gas to be lost during eruption. If I combine the maximum release of SO₂, HCl, and HF during lava transport and explosive activity at Cinder Cone, the amount released into the troposphere is ~11 Mt SO₂, ~0.5 Mt HCl, and ~0.5 Mt HF.

Figure 24: Volatile contents for Cinder Cone (northern California) from olivine-hosted melt inclusions (filled circles) and lava glass (open triangles). The lowest K_2O and TiO_2 concentration melt inclusion was chosen as the best representative of the parental magma composition. FC denotes pure fractionation of crystals; AFC denotes crystal fractionation with assimilation.

The amount of volatile lost during lava flow emplacement is considerable, and greatly increases the exposure risk to volcanic gases during eruption.

6.5. Volatile dispersal within a Gaussian plume

The steady-state Gaussian plume model reveals varying gas concentrations downwind of the vent depending on the instability of the plume. The predominant form of sulfur released during an eruption is SO₂. Both SO₂ and H₂S are released from the magma and their relative abundance largely depends of the oxidation state of the magma. It has been documented during some eruptions that some of the S released from the magma as H₂S oxidizes in the atmosphere to SO₂ (Carroll and Rutherford, 1985, Metrich and Wallace, 2008). In the case of Cl and F, both combine with hydrogen to produce the highly acidic HCl and HF gases, respectively. HCl and HF are highly soluble in water, and thus are of great concern for human, livestock, and agricultural communities.

Figure 25 illustrates how the maximum and minimum SO₂, HCl, and HF concentrations at ground level change with distance from the plume origin. Values for the maximum curves represent a cone with the largest degassed total for a particular volatile. Minimum curve values represent a cone with the least degassed total for a particular volatile. At a distance representative of the length between susceptible communities in central Oregon and northern California and a cinder cone on or near the arc axis, predictions of maximum SO₂ concentrations 25 km downwind of the vent range from 0.006 ppm (unstable) to 1.1×10^{-10} ppm (neutral). Minimum predictions of SO₂ concentrations 25 km downwind of the vent range from 0.005 ppm (unstable) to 8.7×10^{-11} ppm (neutral). Maximum predictions of HCl concentrations 25 km downwind of the vent

range from 2.7×10^{-4} ppm (unstable) to 5.0×10^{-11} ppm (neutral). Minimum predictions of HCl concentrations 25 km downwind of the vent range from 9.3×10^{-5} ppm (unstable) to 1.7×10^{-11} ppm (neutral). Maximum predictions of HF concentrations 25 km downwind of the vent range from 9.3×10^{-5} ppm (unstable) to 4.8×10^{-11} ppm (neutral). Minimum predictions of HF concentrations 25 km downwind of the vent range from 2.9×10^{-5} ppm (unstable) to 1.7×10^{-11} ppm (neutral). From Figure 25 it is obvious that a highly unstable plume produces overall higher concentrations of gases with distance from the vent than a stable plume, but the maximum concentrations are located within 2 km of the vent.

6.6. Implications for hazards

To date, few investigations in the Cascades have focused on the hazards human, animal, and agriculture populations experience as a result of volcanic degassing during an

Figure 25: (next two pages) Predicted ground level volatile concentrations downwind of the vent for the central Oregon and northern California cinder cones for plumes of varying instabilities (a, b). The red line represents the cone with the maximum dissolved volatile content and highest percent degassing. The blue line represents the cone with the minimum dissolved volatile content and lowest percent degassing (excluding 0% degassing). Volatile mass eruption rate (MER) was calculated using the average magmatic MER of Violent Strombolian eruptions (Pioli et al., 2010) and the mass of volatile released during eruption (Equation 5).

explosive mafic eruption. Assessing emissions released into the atmosphere is essential to the understanding and mitigation of their potential effects on local communities and ecosystems (Sawyer and Oppenheimer, 2006).

Volcanoes and their eruptions can result in a wide range of health impacts, arguably more varied than in any other kind of natural disaster (Hansell et al., 2006). Now more than ever, as cities spread into active volcanic areas, human populations are at risk of experiencing volcanic emissions from a range of eruptions of varying size and explosivity. Areas hundreds of kilometers away can also be affected as a result of strong prevailing winds and airborne dispersal of gases and ash (Hansell et al. 2006). Principal studies concerning health hazards from volcanic gases are not well-represented in the literature. Few principal studies have conducted health tests in response to volcanic gas exposure and those that do exist are limited in terms of exposure assessment (Hansell and Oppenheimer, 2004). Most research to date relates to exposures to CO₂, H₂S, and SO₂ from volcanic and geothermal sources. The studies that concentrate on exposure to HCl and HF focus on the complications associated with inhalation or ingestion of ash-adsorbed aerosol particles or highly acidic waters by sheep and other livestock. A literature review of health hazards associated with volcanic gases by Hansell and Oppenheimer (2004) found that <1 to 4% of all volcano-related mortality was due to volcanic gases. A similar review of volcanic incidents by Witham (2005) reported that out of 491 global events, 11% referred to volcanic gases, accounting for 2,016 (2% of the total) of the killed and 2,860 (18%) of the injured people. However, these estimates are only minimum values- the majority of the reports neglected degassing that occurs passively through lava flow transport.

The most common risk of exposure to volcanic gas in humans is respiratory. A portion of all volcanic gases condense and adsorb onto tephra particles within the plume during transport if atmospheric conditions are favorable for gas-liquid phase reactions (Oskarsson, 1980; Gilbert et al., 1991). These gases react with the silicate glass and form acidic salts, which can easily dissolve with water, or in the case of livestock, in their digestive system (Oskarsson, 1980; Cronin et al., 2003; Horwell and Baxter, 2006). Table 7 shows a compilation of hazardous SO₂, HCl, and HF levels. Human intake values reported for SO₂ were gathered during active eruptions and assessed using the World Health Organization (WHO) air quality standards (WHO, 1984), whereas values for HCl and HF are a combination of hazardous drinking levels from Cronin and Sharp (2002) and concentrations of maximum occupational exposure limits set by the Occupational Safety and Health Administration (OSHA) (OSHA, 1989). SO₂, HCl, and HF can all cause acute irritations to the membrane lining of the eyes, nose and throat. More seriously, these volcanic gases can cause symptoms such as headaches, dizziness, vomiting, visual disturbances, bronchitis, pulmonary edema, and in grave situations, asphyxiation (Heggie, 2009).

Plants and animals can also be affected by volcanic gases, but by other means than in humans. Animal contact with volcanic gases often occurs through ingestion. Cronin et al. (2003) documented the relationship between grazers and fluorides adsorbed onto the ash particles that has fallen onto the pastures. Ingestion of these fluoride salts caused symptoms of dental fluorosis and in total killed at least 2,000 grazing animals. Like humans, fluorosis in livestock causes deterioration in teeth as the enamel fails to mineralize and causes dissolution of bones or abnormal bone growth (Suttle, 2010).

Table 7: Compilation of published exposure limits and medical symptoms of SO₂, HCl, and HF contamination in humans, livestock, and agricultural crops

	life form	*maximum exposure limit	**specific symptoms	references
<u>SO₂</u>	human	177 ppm for 10 min; 7 ppm for a 24-hr period	1 ppm induces asthmatic reponse; 6-12 ppm immediate irritation to the nose and throat	* World Health Organization **World Health Organization; Heggie (2009)
	livestock	unknown	3-4 g S kg ⁻¹ per day reduction in appetite and growth rate	**Suttle (2010)
	crops	>60 ppbv	<6 ppbv no visible damage; <40 ppbv observable necrosis to trees and shrubs; >62 ppbv fatality	*Delmelle et al. (2002) **Delmelle et al. (2002); Davidson and Weinstein (2006)
<u>HCl</u>	human	5 ppm for a 24-hr period	>35 ppm irritation to the nose, throat and larynx; >70 ppm acute laryngeal spasm and pulmonary edema	*OSHA ** Heggie (2009)
	livestock	>60 mg Cl kg ⁻¹ per day	unknown	* Suttle (2010)
	crops	unknown	unknown	
<u>HF</u>	human	3 ppm for 10-hr period; 1.5 ppm in drinking water	50-250 ppm lethal for a 5 min period; drinking water > 1.5 ppm mottling of teeth, 20-40 ppm skeletal fluorosis	*OSHA; Cronin and Sharp (2002) **OSHA
	livestock	>60 mg F kg ⁻¹ per day	40-100 µg per body weight chronic fluorosis; >100 µg per body weight fatal;	*Suttle (2010) **Cronin et al. (2003)
	crops	unknown	0.25-0.3 µg/m ³ visible necrosis	**Davidson and Weinstein (2006)

Fluorine is absorbed into the livestock's milk and ingestion can be harmful to calves/lambs and humans. Plants can be affected by leaf or fruit injury due to direct contact with gaseous voges (aerosol fog) or ingestion by uptake through roots. Once inside of a leaf, fluorine ions are transported to the cell walls where they accumulate in the tips of leaves or fruits (Davidson and Weinstein, 2006). This leads to yellowing and possible death of cell membranes. Animal and plant intake values reported for SO₂, HCl, and HF were gathered after eruptive episodes and hazardous intake levels were gathered through trace analysis of bones, teeth, and plant tissues. The danger from drifting volcanic gases is commonly a short-range one (within the vicinity of the cinder cone), but farther away damage is mostly caused by aerosols transported by tephra (Thordarson, 1979). However, vegetation and livestock can experience long lasting effects as the acidic aerosols and salts are incorporated into soils (Delmelle et al., 2003) and dissolved into accessible water sources (streams, ponds, groundwater, etc.).

The Gaussian plume model predicts volatile concentrations downwind from the vent to be dilute enough to not pose a significant hazard to surrounding communities (Figure 25). Based on the distal tephra deposits from isopachs of McKay (2012) (Figure 5) and evaluation of smoke stake plume stabilities (Hanna et al., 1981; EPA, 2012), I suggest the moderately unstable plume stabilities best describe the plume behavior of cinder cones in central Oregon and northern California. Gas concentrations for these plumes fall far below the accepted exposure limits listed in Table 7. For the purpose of hazard prediction, I also calculated the gas concentrations downwind of the vent for a MER of 10⁵ kg/s. Pioli et al. (2009) shows that this MER is representative of Violent Strombolian to Subplinian eruptions, characterized by voluminous and sustained ash

columns ~10-20 km in height. The predicted S, Cl, and F concentrations downwind of the vent for an eruption of MER of 10^5 kg/s are a magnitude greater than the concentrations initially calculated, however these concentrations are still below the maximum exposure limits (Figure 26).

Evaluation of the Laki eruption from 1783-1784 reveals concentrations of S, Cl, and F downwind of the vent that far exceed the concentrations released during the Cascades cinder cone eruptions (Figure 27). I estimated the magmatic fluxes of the Cascades cinder cones to be 10^4 kg/s, such that explosive and effusive activity was sustained (Pioli et al., 2008). Unlike the Cascades eruptions, the magmatic flux of Laki has been extrapolated from physical assessments of tephra fall and averages 2.0×10^6 kg/s (total eruption volume) and 5.3×10^4 kg/s (tephra volume) for the 8 month duration of activity. However, 90% of the eruption volume was released during the first 5 months of explosive activity (Thordarson et al., 1996). Crystallization was minimal (<4%) at Laki, therefore Thordarson et al. (1996) did not adjust their volatile concentrations based on crystal percentages of the matrix glasses. Parental volatile concentrations between Laki

Figure 26: (next two pages) Predicted ground level volatile concentrations downwind of the vent for the central Oregon and northern California cinder cones for plumes of varying instabilities (a, b) using an eruptive volume of 10^5 kg/s and 10^4 kg/s. The dashed red line represents maximum gas concentration and the blue dashed line represents the minimum gas concentration using 10^5 kg/s. The other symbols are the same as in Figure 25. Refer to Figure 25 for a more detailed explanation of volatile MER.

Figure 27: Predicted volatile concentrations downwind of the vent for the 1783-1784 Laki eruption for a plume of moderate instability that degassed solely at the vent (top) and both at the vent and passively via lava emplacement (bottom). The curves are average concentrations downwind of the vent based on the mass of volatiles released and the total DRE erupted volumes for tephra and all erupted products (Thordarson et al., 1996).

and the Cascades cinder cones are relatively similar, so if a higher volume mafic eruption ever occurs in Cascades in the future, residents of nearby communities may experience seriously harmful concentrations of volcanic gases.

Previous physical analysis by McKay (2012) has shown the occurrence of a Subplinian in character eruption from a mafic cone, Sand Mountain, in the central Oregon Cascades. Though I was unable to match melt inclusion compositions to tephra compositions because of a complex history of compositionally different melt batches mixing in the system, if I assume homogeneity for the different melt batches, I can speculate at the maximum possible release of volatiles during eruption. Olivine-hosted melt inclusions from Sand Mountain recorded volatile concentrations of S (2220-430 ppm), Cl (1860-610 ppm), and F (710-310 ppm). Matrix glass recorded up to ~99% degassing of S, ~73% degassing of Cl, and ~23% degassing of F during the explosive phase of eruption. Using the maximum eruptive volume estimated by McKay (2012), this equates to a release of 7.6 Mt SO₂, 2.9 Mt HCl, and 0.28 Mt release of HF (Appendix G). These release values are roughly an order of magnitude larger than those released by the cinder cones in central Oregon and northern California. The geochemical and physical analysis on Sand Mountain shows that future mafic eruptions in the central Oregon Cascades may have the eruptive power and exsolved volatile concentrations capable of creating a regional hazard.

While not the focus of this study, it is important to note the hazardous effects from tephra fallout that future mafic activity poses to (1) public health, (2) agriculture, and (3) local transportation and infrastructure. Volcanic ash is the most widely distributed eruption product, affecting regions km's away. Airborne ash particles <10

μm can be inhaled in the upper lungs and cause acute asthmatic conditions or bronchitis. Particles $<4 \mu\text{m}$ in diameter are referred to as “respirable” and have the greatest toxic potential, yet diseases such as silicosis or lung cancer often require high levels of cristobalite (3-5 wt%), something mafic eruptions are incapable of crystallizing (Horwell and Baxter, 2006; Hillman et al., 2012). Epidemiological studies established that areas with high levels of airborne ash (daily average total suspended particulates (TSP) of $3000\text{--}33000 \mu\text{g}/\text{m}^3$) experienced a 2–3-fold increase in hospital admissions and 3–5-fold increase in emergency room visits for respiratory conditions (Hansell et al., 2006). Agriculture can experience heavy impacts from tephra dispersal. The effects of cinder cone eruptions upon nearby agricultural communities were studied by Ort et al. (2008) and their findings indicate a complete disruption to agricultural lands immediately after eruption with $>30 \text{ cm}$ deposition of tephra. In semi-arid regions, natural processes to breakdown tephra and incorporate it into the soil can take up to 1,000 years. This process can be hastened to a few decades in a more humid environment (Ort et al., 2008). Lastly, airfall can greatly affect the public sector by causing power outages, decreasing water quality through acidification or turbidity, clogging drainage networks, collapsing infrastructure, and reducing visibility, traction, and functionality of major roads and air traffic (Ort et al., 2008; Heggie, 2009; Wilson et al., 2012).

CHAPTER VII

CONCLUSIONS

I have investigated the degassing history of seven prehistoric mafic eruptions in central Oregon and northern California. The eruptions are characterized by Strombolian to Violent Strombolian eruptive activity, and produced $\sim 0.03\text{-}0.36 \text{ km}^3$ of basalt to basaltic andesite scoria, tephra, and lava. Olivine-hosted melt inclusions constrain the melt compositions, including volatile content, at each cone. Analysis of olivine-hosted melt inclusions allowed me to compare and contrast the crystallization and degassing history of each cone, and the data reveal a complicated history of magma evolution through fractional crystallization and crustal assimilation. The melt inclusions also show volatile values elevated above MORB concentrations (Wallace, 2005). Compared to matrix glass, the individual eruptions degassed 88-100% sulfur, 0-49% chlorine, and 0-50% fluorine during explosive activity. S was efficiently lost during all eruptions, but Cl and F degassed to a much lesser extent due to their relatively high solubility, allowing them to largely remain in the magma. Three of the seven cones did showed no degassing of F. When converted into megatonnes released into the atmosphere in gas form, each cone emitted $\leq 4.5 \text{ Mt SO}_2$, $\leq 0.2 \text{ Mt HCl}$, and $\leq 0.2 \text{ Mt HF}$. Maximum volatile contents for eruptions in central Oregon and northern California are similar to volatile contents from the mafic eruptions of Laki and Cerro Negro (Thordarson et al., 1996; Portnyagin et al., 2012; Roggensack et al., 1997). Degassing calculations and a Gaussian plume model predicts a Laki eruption to emit hazardous levels of S, Cl, and F considerable distances downwind from the vent. Hazards documented at Laki and Cerro Negro are extensive,

and risk ranges in form of agriculture and livestock fatality, atmospheric pollution, and accumulation of tephra fall on agricultural crops, roads, and infrastructures (Thordarson et al., 1996; Hill et al., 1998; Thordarson and Self, 2003; Delmelle et al., 2002).

My results of volatile degassing from prehistoric mafic volcanism in the Cascades provides reassurance that the levels of volcanic gases in neighboring cities were not high enough at time of the eruption to present an acute or severe health hazard to nearby residents. If future eruptions present themselves like those of the cinder cones of this study there will be no need to evacuate residents on grounds of harmful gas concentrations. However, if future eruptions behave like that of Sand Mountain or Laki, then mitigation for increased airborne concentrations of SO₂, HCl, and HF and high volumes of tephra should be planned accordingly.

APPENDIX A

DETAILED LIST OF SAMPLE LOCATIONS AND DESCRIPTIONS

Collier Cone (Collier33B, Collier33D)

Collier Cone is located on the NW flank of the North Sister stratovolcano, ~3km NNW of the summit, on the axis of the High Cascades arc in Central Oregon (Figure 3). The eruption that built the 150 m high scoria cone occurred 1600 ± 100 years B.P (based on ^{14}C dating) (McKay, 2012; Sherrod et al., 2004). The cone is breached to the west and flows of basaltic andesite, andesite, and dacite lava (Sherrod et al., 2004) exited the breach and flowed down valley to White Branch Valley, ~13 km away. The lavas contain troctolite xenoliths that are interpreted to be mafic cumulates, as well as silicic xenoliths similar in composition to the Obsidian Cliffs, a dacitic to rhyolitic flow originating from Middle Sister (Schick, 1994). Addition of a silicic contaminant can explain much of the compositional variation of Collier Cone melt inclusions (Ruscitto, 2011). Table 2 lists the major and minor element concentrations for the silicic xenoliths near North Sister (Schick, 1994). The lava flows partially cover the western edge of the nearby Four-in-One Fissure tephra blanket, stratigraphically placing the eruption of Collier Cone after that of Four-in-One Fissure. The tephra blanket is exposed east of the vent where it lies stratigraphically above a tephra unit from the Yapoah eruption (Sherrod et al., 2004). The total volume of the tephra is 0.037 km^3 over a 14.7 km^2 area. The total volume of lava erupted from Collier Cone is 0.154 km^3 . The total DRE eruptive volume for Collier Cone is 0.154 km^3 (McKay, 2012). Based on volume and areal dispersal

calculations by McKay (2012), the eruption style of Collier Cone was mainly Strombolian, but had episodes of Violent Strombolian activity.

Yapoah Crater (Yo061E)

Yapoah Crater is located ~6 km N from the summit of North Sister and ~3km N of Collier Cone (Figure 3). The cone is approximately 85 m high and a small breach to the NW side of the cone fed basaltic andesite lava flows that extended ~12 km NNE around the flank of Belknap shield volcano. No absolute age date exists for Yapoah Crater, but a relative age date (based on stratigraphy) from the eruptions of Little Belknap Crater and Four-in-One Fissure brackets the age for the Yapoah eruption at 2883±175 B.P. to 1980±160 B.P (based on ¹⁴C dating; Sherrod et al., 2004). Small lenses of tephra are visible to the east of Yapoah Crater, but to date no isopach has been constructed for Yapoah. Therefore, the volume of tephra, lava and total eruptive products are not known. Because no isopach exists for Yapoah Crater, no inference about eruption style can be made. However, based on grain size and grain sorting work by McKay (2012) for other cinder cones in the High Cascades and the Oregon Cascades back arc, I propose Yapoah Crater may have erupted with similar Strombolian-like characteristics.

Four-in One Fissure (Fo0803D3)

Four-in-One Fissure is a 75 m series of cones located ~6 km NNW of the summit of North Sister and ~2 km WSW of Yapoah Crater (Figure 3). It consists of four contiguous cones erupted from a linear fissure system, trending N 10° E (Sherrod et al., 2004). The best eruption age estimate is based on radiocarbon dating and places the

onset of activity to be 1980 ± 160 years B.P. The basaltic-andesite to andesite flows of Four-in-One Fissure (Sherrod et al., 2004) breached the cone to the NW and flowed a short distance of ~ 4 km towards Belknap Crater. Tephra is again exposed to the east of the vent where it is overlain by Collier Cone lava. The tephra east of the vent stratigraphically lies above a tephra sequence from the Yapoah Crater eruption. McKay (2012) calculates the extent of the tephra blanket to be 0.002 km^3 over an area of 1.36 km^2 , but these are minimum estimates as a complete isopach has yet to be obtained. The volume of lava erupted is estimated to 0.036 km^3 . The minimum total eruptive DRE volume for Four-in-One Fissure is 0.032 km^3 . Based on volume and areal dispersal calculations by McKay (2012), the eruption style of Four-in-One Fissure was likely Hawaiian to Strombolian.

Garrison Butte (GB072)

Garrison Butte is a 41 m high cone located ~ 30 km NE of the North Sister summit, and ~ 7 km E of Black Butte shield volcano (Figure 4). Garrison Butte lies along strike of a closely clustered chain of cinder cones trending $N 40^\circ W$. Unlike Collier Cone, Yapoah Crater, and Four-in-One Fissure, Garrison Butte resides in the Cascade back arc, off-axis of the arc by ~ 24 km to the east. No physical, petrological or radiogenic studies have been conducted on Garrison Butte, therefore eruptive volume and age are not known. The cone of Garrison Butte and its associated lava flows are heavily vegetated, and therefore I would expect Garrison Butte to be older than Yapoah Crater.

Cinder Cone (LCC2, LCC9)

Cinder Cone is an aptly named cinder cone standing ~160 m tall and located in the Lassen Volcanic Field in Northern California (Figure 5). It lies adjacent to Pilot Butte and ~17 km ENE of Lassen Peak. The cone sits atop an older, destroyed cone, thought to be the primary vent in the earlier stages of eruption. The eruption of Cinder Cone is thought to be segmented into three distinct episodes that spanned a 300-year period (USGS, 2000). These periods are labeled by their associated lava flow (oldest to youngest) - Old Bench lava flow, Painted Dunes lava flow, and Fantastic lava beds. Radiocarbon dating by Clynne et al. (2002) dates the time of eruption at 264 ± 28 B.P (based on ^{14}C dating). The composition of lavas at Cinder Cone are basalt to basaltic-andesite and contain quartz phenocrysts and granitic xenoliths. The quartz xenocrysts and granitic xenoliths are suggested to be from a Mesozoic granite, possibly akin to the Sierra Nevadas, buried beneath the Lassen region. The granitic xenoliths have major and trace element compositions that are typical of the Sierra Nevada granitoids (Borg and Clynne, 1998). Table 2 lists the major and minor element concentrations for the Lassen granitic xenoliths (Borg and Clynne, 1998). The lavas damned a prehistoric lake, which formed the current Snag and Butte Lakes. Because of Cinder Cone's young age the tephra deposit is well-preserved. Tephra is exposed mainly NE of the vent, but can be found radially around the cone. The total volume of tephra is 0.043 km^3 while the total eruptive volume of lava is 0.08 km^3 (Clynne AGU 2011, Marks, 2012). The total eruptive DRE volume for Cinder Cone is estimated to be 0.36 km^3 (Clynne AGU 2011). Based on the isopach, grains size, and grain sorting Cinder Cone erupted in a Strombolian to Violent Strombolian style (Marks, 2012).

Basalt of Old Railroad Grade (BORG)

Basalt of Old Railroad Grade (BORG) is a cinder cone within a larger chain of cones trending N 35° W, known as the Basalts of old railroad grade, and is located in the Caribou Volcanic field of Northern California (Figure 5). The cone edifice of BORG is roughly ~80 m high and is located ~14 km NNE from Cinder Cone and ~30 km NE from the summit of Lassen Peak. The cone is relatively intact; a vegetated lava flow is visible to the NW of the vent and tephra is exposed in small lenses NW of the vent. The Basalts of old railroad grade include four eruptive units (bg1-bg4), of which BORG is considered a sub unit within bg3. The Basalts of old railroad grade are classified into a larger eruptive group known as the Poison Lake Chain (Muffler et al., 2011). A complicated stratigraphic history of the Poison Lake Chain reveals the chain most likely erupted in two short periods, separated by movement on a normal fault associated with the Hat Creek fault system. The earliest eruptions of the Basalts of old railroad grade are suggested to have begun at ~100 Kya (based on $^{40}\text{Ar}/^{39}\text{Ar}$ dating; Muffler et al., 2011). The commencement and termination of eruptions that formed BORG have yet to be determined, but $^{40}\text{Ar}/^{39}\text{Ar}$ dating by Muffler et al. (2011) on unit bg4 of the Basalts of old railroad grade and the next stratigraphically youngest unit, the Bidwell Spring Chain, reveal a potential eruption age that ranges from 102.4 ± 11.4 to 46.3 ± 3.4 Kya. No description of distal tephra exists, however, the total volume of erupted lava is 0.059 km^3 over a 2.97 km^2 area. The total erupted DRE volume, excluding tephra volume, erupted from BORG is estimated to be 0.07 km^3 (Muffler et al., 2011). Because distal tephra has not been described, the erupted style for BORG is unknown.

Basalt of Highway 44 (BAS44)

Basalt of Highway 44 (BAS44) is located in the back arc basin of Northern California. BAS44 is situated ~10 km WSW from BORG and ~21 km NE of the Lassen Peak summit (Figure 5). BAS44 stands ~40 m high and a breach on the SE side of the cone is visible. A small, vegetated lava flow is present flowing from the SE breach, but it is overlain by a visibly younger lava flow erupted from a cinder cone situated on the SE flank of West Prospect Peak shield volcano (not dated). The flows are also bounded to the west by the western edge of the Hat Creek Graben. No physical, petrological or radiogenic studies have been conducted on BAS44, therefore eruptive volume, eruptive style, and age are not known.

APPENDIX E

GAUSSIAN PLUME STABILITY CONSTANTS AND DEFINITIONS

Definitions of plume stability from Hanna et al. (1982)

- | | |
|--|--|
| <p>A: Extremely unstable conditions
 B: Moderately unstable conditions
 C: Slightly unstable conditions</p> | <p>D: Neutral conditions†
 E: Slightly stable conditions
 F: Moderately stable conditions</p> |
|--|--|

Surface wind speed, m/sec	Daytime insolation			Nighttime conditions‡	
	Strong	Moderate	Slight	Thin overcast or > 4/8 low cloud	≤ 3/8 cloudiness
<2	A	A-B	B		
2	A-B	B	C	E	F
4	B	B-C	C	D	E
6	C	C-D	D	D	D
>6	C	D	D	D	D

*From F. A. Gifford, *Turbulent Diffusion-Typing Schemes: A Review*, *Nucl. Saf.*, 17(1): 71 (1976).

†Applicable to heavy overcast day or night.

‡The degree of cloudiness is defined as that fraction of the sky above the local apparent horizon that is covered by clouds.

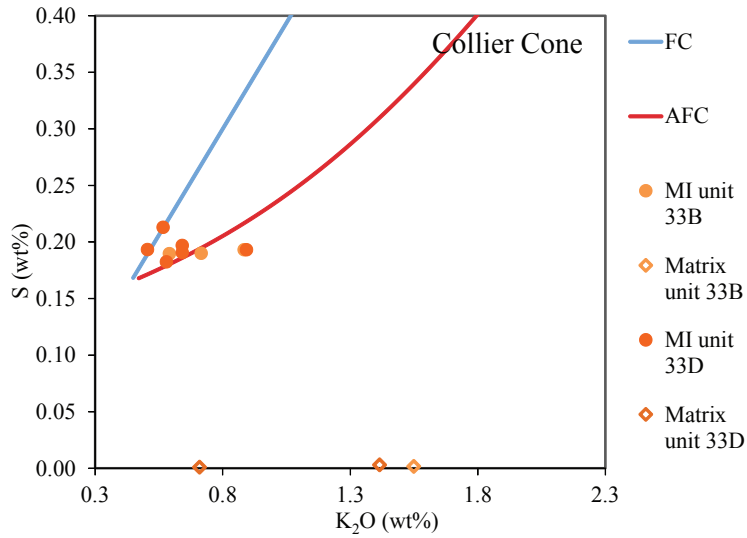

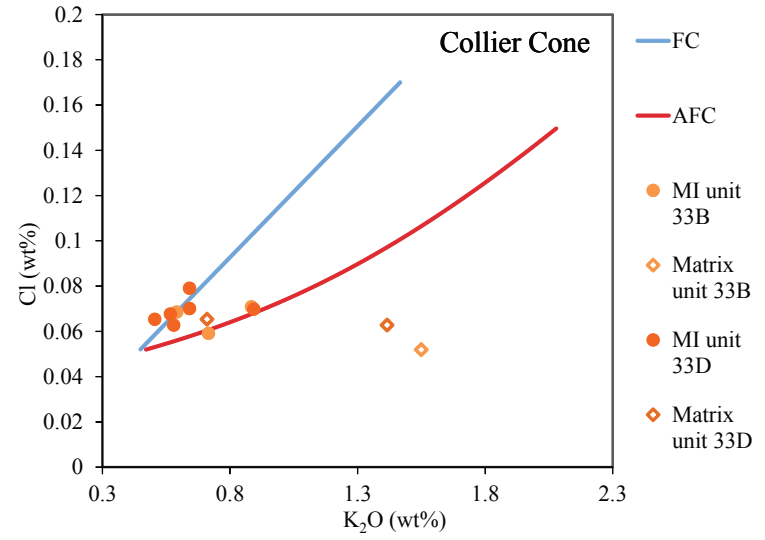

Gaussian plume constants for varying plume stability from Guenther (2010)

Plume Stability	x (km)	a	b	c	d
<u>Unstable</u>	<0.1	122.80	0.94	24.17	2.53
	0.10-0.15	158.08	1.05	24.17	2.53
	0.16-0.20	170.22	1.09	24.17	2.53
	0.21-0.25	179.52	1.13	24.17	2.53
	0.26-0.30	217.41	1.26	24.17	2.53
	0.31-0.4	258.89	1.41	24.17	2.53
	0.41-0.5	346.75	1.73	24.17	2.53
	0.51-3.11	453.85	2.12	24.17	2.53
	>3.11	+	+	24.17	2.53
<u>Moderately Unstable</u>	<0.20	90.67	0.93	18.33	1.81
	0.21-0.40	98.48	0.98	18.33	1.81
	>0.40	109.30	1.10	18.33	1.81
<u>Slightly Unstable</u>	All	61.14	0.91	12.50	1.09
<u>Neutral</u>	<0.30	34.46	0.87	8.33	0.72
	0.31-1.00	32.09	0.81	8.33	0.72
	1.01-3.00	32.09	0.64	8.33	0.72
	3.01-10.00	33.50	0.60	8.33	0.72
	10.01-30.00	36.65	0.57	8.33	0.72
	>30.00	44.05	0.51	8.33	0.72

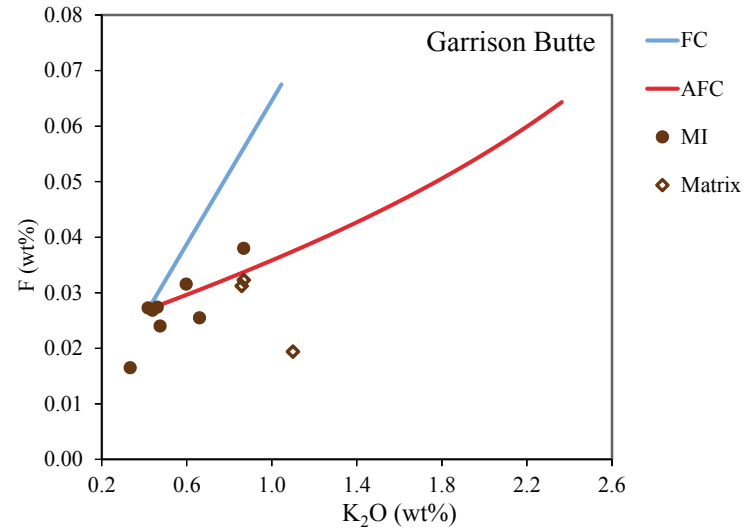

+ if $\sigma_z > 5000$ m, σ_z is set to 5000 m

APPENDIX F

SULFUR, CHLORINE, AND FLUORINE EVOLUTION AND DEGASSING

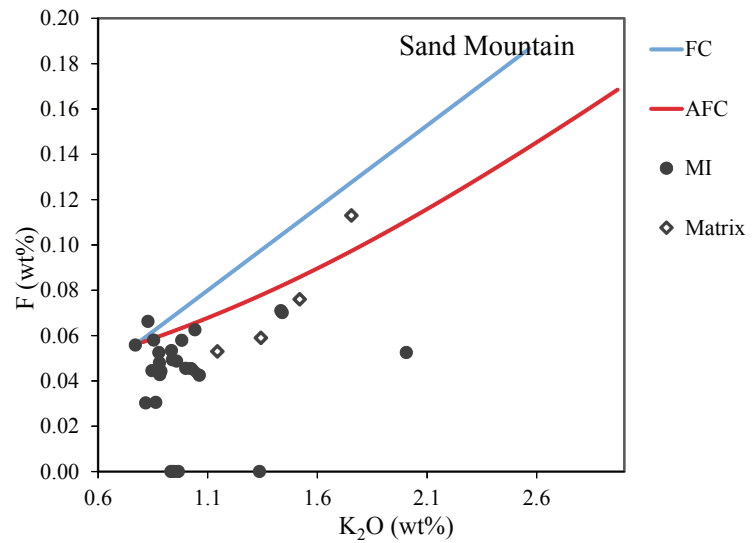

APPENDIX G
MASS OF SO₂, HCL, AND HF DEGASSED DURING EXPLOSIVE ACTIVITY AT
SAND MOUNTAIN

	C_{adj} (wt %)	C_{matrix} (wt %)	V_T (km³)	m_T SO₂ (Mt)	% degassed
Sand Mountain	0.253	0.001	0.75	7.55	100
	C_{adj} (wt %)	C_{matrix} (wt %)	V_T (km³)	m_T HCl (Mt)	% degas
Sand Mountain	0.252	0.068	0.75	2.93	73
	C_{adj} (wt %)	C_{matrix} (wt %)	V_T (km³)	m_T HF (Mt)	% degas
Sand Mountain	0.068	0.053	0.75	0.28	23
	% Crystallinity	% Crystal Fractionation			
Sand Mountain	25	40
