Introduction

The Oregon coastline has many intertidal species of crab, ranging from small anomuran porcelain crabs, to large *Cancer productus* and *magister* crabs. Most of these crabs are fairly distinct in their appearance, but two stand out because of their similarity. *Hemigrapsus nudus* (purple shore crab) and *Pachygrapsus crassipes* (lined shore crab) are fairly similar in shape and size, and usually it takes a close look to distinguish between the two species. The most apparent difference is that *Hemigrapsus* has purple spots with a white background on its chelipeds, while *Pachygrapsus* has a striped carapace and un-dotted chelipeds.

Since the two species are so similar in appearance, it would be expected that both crabs would have similar speeds when avoiding capture, but this is not the case. When a rock is overturned and a *Hemigrapsus* is exposed, it is fairly easy to capture before it reaches cover. When a *Pachygrapsus* is exposed in a similar manner, it is very difficult to catch the crab before it finds a crevice or other rock to hide in. The difference in speed between the two crabs is considerable.

The purpose of this experiment is to test the hypothesis that the difference in speed arises from a physical difference between the two crabs. Three factors will be explored to try to find a physical difference between the two crabs that could at least partially explain the difference in speed between the two crabs. First, the relationship...
between body mass and leg mass will be tested. Perhaps a crab with a higher leg mass to total body mass ratio would have an advantage through higher leg strength. The second test will be overall leg length compared to carapace width. Since the crabs will all be different size, the ratio of leg length to carapace width will hopefully give a way of comparing relative leg length between species. The third will be individual segments of the leg compared to the carapace width, to see if leg composition plays a role in speed.

Methods

Five *Hemigrapsus*, and five *Pachygrapsus* crabs were collected over a several day period (July 5-8) from the rocks across Boat Basin road from OIMB, and from South Cove at Cape Arago State Park. Selecting factors for the crabs were size (the largest 5 of each species collected were used) and the crabs needed all their limbs intact. The crabs were frozen and thawed for handling purposes. A digital scale accurate to .01g was used for weight measurements, and a hand caliper marked at 1mm intervals was used for all distance measurements. The crab was dried of all excess moisture and weighed. Carapace width and total leg length for the four walking legs was then measured by caliper. Each of the five walking leg segments was then measured by caliper. The eight walking legs were then removed by hand, and weighed. A diagram of leg number and measurement methods is on page 5.

Results
The first of the three tests was the leg weight / body weight test. Both crabs had an average of 23% for leg/body weight. (See top of page 6 & bottom of page 10 for graph) The second test was overall leg length compared to carapace width. For the *Pachygrapsus*, leg one on average was 109% the width of the carapace, leg two, 131%, leg three, 125%, and leg four at 108%. The *Hemigrapsus* results were 101% for leg one, 122% for leg two, 119% for leg three, and 88% for leg four. (See bottom of page 6 & top of page 10 for graph) The third test was leg segment / carapace width. Page 7 details the average segment/carapace ratio by leg segment and leg number for each species. Pages 8-9 graph the average ratios by species and leg number. Pages 11-15 show individual *Hemigrapsus* data, summarized on page 16. Pages 17-21 show individual *Pachygrapsus* data, summarized on page 22. On average, *Hemigrapsus* has a longer dactyl except on leg 4. *Pachygrapsus* has a longer propodus on each of the legs. *Hemigrapsus* has a longer carpus on legs 1 & 2, but *Pachygrapsus* has a longer caprus on legs 3 & 4. *Pachygrapsus* has an equal merus on legs 2 & 3, and a longer merus on 1 & 4. *Hemigrapsus* has an equal Ischium on legs 1 & 2, and a longer ischium on legs 3 & 4.

**Conclusion**

It seems logical to discard leg weight as a factor that could explain the difference in speed between the two species. In this test the ratio was the same to a hundredth of a gram, a fairly convincing statement. Overall leg length is a more likely possibility. The *Pachygrapsus* in all legs had longer legs proportional to its carapace. Every step the *Pachygrapsus* takes, it covers more ground (assuming that each leg rotates an equal number of degrees) and should make its motion faster. Coupled with a shorter ischium
on average (which could increase muscle leverage for rotation) this is a plausible explanation. The *Pachygrapsus* also has a longer merus on average. The merus contains the muscle that is connected to the carpus, the other main joint the leg. The longer merus may give *Pachygrapsus* more muscle mass to extend and contract the carpus. This would give *Pachygrapsus* another advantage in speed over *Hemigrapsus*. The other joints are less important in locomotion, since they do not pivot to the degree that the ischium-body joint and merus-carpus joint do. It is probable that a large amount of the difference is behavioral, *Pachygrapsus* is a higher intertidal animal than *Hemigrapsus*, and is probably subject to predation by mammals and birds more than *Hemigrapsus* is. Quick reflexes and speed would seem to be more important for *Pachygrapsus*’ survival than *Hemigrapsus*. A test on behavior, specifically predator avoidance would shed more light on the issue.

The difference in speed between *Pachygrapsus crassipes* and *Hemigrapsus nudus* is, at least in part, due to physical differences. Specifically overall leg length and ischium and merus lengths. Weight is equivalent between the crabs and is not a significant factor.
weights and total leg lengths all units in mm or g
